Soil biological activity is either directly influenced by the supply of food substrates by organic mulches or indirectly influenced by both organic and inorganic mulches through altering soil hydrological and thermal regimes. The activity and diversity of soil organisms are influenced by mulch quality and application rates. Soil microorganisms (bacteria, fungi and actinomycetes) and fauna (earthworm, millipede, centipede etc.) help in decomposing soil organic matter and hence enhance nutrient availability. However, mulching with materials of high C:N ratio results in nitrogen immobilization. Changes in soil physicochemical properties during mulching can promote changes in microbial community structure and its metabolic function. Zhang et al. (2020) reported that bacterial communities were significantly higher (3.2%) in peanut (*Arachis hypogaea* L.) mulched soil than that under polyethylene film (1.2%) because of the relative abundance of *Nitrospirae* in the peanut mulched soil. Similarly, the fungal communities were significantly higher (33.7%, 21.9%) in peanut hull mulched soil than that in polyethylene film mulched soil (14.9%, 6.5%), due to the relative abundance of *Mortierellomycota* and *Basidiomycota*. Peanut hull mulching increased the diversity of fungal communities at 0–20-cm soil depth and the diversity of bacterial communities at 20–40-cm soil depth. At the microbial functional level, there was an enrichment of bacterial functional features, including amino acid transport, and metabolism and energy production and conversion, and there was an enrichment of fungal functional features, including undefined saprotrophs, plant pathogens and soils apotrophs. They concluded that organic mulching had a positive regulatory effect on the soil bacterial and fungal communities and ecosystem functions, and so, is more suitable for tea (*Camellia sinensis* (L.) Kuntze) plantations. Rabary et al. (2008) reported that soil β -glucosidase and acid phosphatase activities were significantly higher for the direct seeding mulch-based systems using crop residues than for those using living mulches in Madagascar. Application of *Trichoderma viride* together with waste mulch in ratoon sugarcane increased contents of organic C, available P and microbial biomass of soil. The residue decomposition and growth promotion abilities of *Trichoderma* produced a synergistic effect with mulch from waste compared with its burning and removal. With degradation, crop residue mulch served as a source of energy for enhanced multiplication of soil bacteria and fungi and provided suitable niches for plant–microbe interaction. Trash mulching together with microbial consortia containing *Gluconacetobacter diazotrophicus*, *Trichoderma viride* and *Pseudomonas fluorescens* effectively improved soil quality properties, and sugarcane and sugar yields in a multi ratooning system. (Yadav et al., 2009). Mulching with organic residues of weeds like wild sage (*Lantana camara* L.) or eupatorium (*Eupatorium adenophorum* Spreng.) under conservation tillage practices enhances the earthworm population with increased food substrate and better hydrological and thermal regimes under the mulch (Acharya et al., 1998).

Effect of mulching on the environment

Intensive plough tillage (PT), use of agricultural chemicals and the burning of crop residues are major farm activities that emitting greenhouse gases (GHGs). On the other hand, no till (NT) and crop residue retention improve soil structure and enhance C sequestration and reduce GHG emissions. With an estimated annual global production of crop residues at 3.76 Pg (Lal, 2005),

conversion of 15% of C in the residues into stable SOC fractions implies C sequestration of 0.15–0.175 Pg year⁻¹. Chatterjee et al. (2018) reported that application of wheat residue mulch in a maize crop significantly increased the total organic carbon (TOC) concentration by 14.9% at 0–5-cm soil depth compared to the no mulch treatment in a sandy loam soil. Water stable aggregate-associated carbon concentration in large macro- and micro-aggregates increased significantly by 16.7% and 11.8%, respectively with crop residue mulching. Application of crop residue mulch also resulted in a significant increase in labile and non-labile pools of carbon at 0–5-cm soil depth compared to the no mulch treatment. This increase in TOC and the non-labile pool of OC will facilitate sequestration of SOC and will contribute to reducing GHG emissions to the atmosphere and thus reduce global warming. Nawaz et al. (2017) reported that on a silt loam soil mulching reduced bulk density and improved total soil porosity. More TC (16.16 g kg⁻¹), SOC (8.36 mg L⁻¹) and soil microbial biomass carbon (152 µg g⁻¹) were recorded in soil under NT than plough tillage (PT). Mulch application also decreased soil temperature (0–5 cm) and penetration resistance (0–60 cm). Adoption of long-term NT reduced the GHG emission. Average fluxes of GHGs under NT were 1.84 g CO₂ –C m⁻² day⁻¹, 0.07 mg CH₄–Cm⁻² day⁻¹ and 0.73 mg N₂O–Nm⁻² day⁻¹ compared with 2.05 g CO₂–Cm⁻² day⁻¹, 0.74 mg CH₄–Cm⁻² day⁻¹ and 1.41 mg N₂O–Nm⁻² day⁻¹, respectively, for PT. Mulching had no impact on CO₂ and CH₄ (methane) emissions but enhanced N₂O (nitrous oxide) emissions.

Effects on crop growth and input-use efficiency

Modification of crop growth

The effect of mulches on crop growth depends upon the combination of climate, type of crop and soil. Mulching influences three principal factors affecting crop growth, i.e., weed competition, seedling emergence and root growth, which influence crop productivity.

Weed competition

Straw mulching suppresses weed growth through delayed emergence, reduced weed count and a smothering effect. Weed control efficacy depends on the type of mulch material used. Black plastic mulches are more effective for weed control than organic mulches in thin layers as light does not penetrate through them.

Seedling emergence

Moisture deficit or unfavorable soil temperature in the seed zone limit seedling emergence even though there may be sufficient water lower in the soil profile. Mulch keeps the surface layers wetter for longer, which enhances seed germination and seedling emergence. The time required for emergence initiation and maximum emergence are shorter under mulches. Straw mulch significantly increases percentage of seedling emergence both under dry and rainfall situations (Prihar, 1986). Under dry conditions, seedling emergence increases due to lower maximum temperature and reduced evaporation losses under mulches, whereas under rainfall conditions seedling emergence increases due to retardation of crust formation, which otherwise hampers seedling emergence.

Root growth

Mulching favorably influences root growth and distribution in the upper soil layer due to favorable soil temperature and higher soil water content under mulches. Higher soil water content in the surface layer reduces the mechanical resistance to growing roots. Application of organic mulches to the previous standing crop helps in conserving and carrying over residual soil moisture at the time of sowing of the subsequent rainfed crop, leading to better root proliferation and higher crop yield, in regions where weather starts cooling in the post rainy season (Table 5).

In Alfisols of the north western Himalayas favorable effects of no-tillage with mulch on root growth was recorded compared to no-tillage (NT) without mulch in a maize–wheat sequence (Acharya and Sharma, 1994). The no-tillage without mulch showed a significant increase in the bulk density at 0–0.15-m depth. Mulching with pine needle at 10 t ha⁻¹ with NT, however, prevented compaction of the untilled layer at the surface and showed a significantly lower bulk density at the surface (0.15 m) depth. It was interesting to note that, even after heavy rain, no surface stagnation of rain water at any time was observed in plots under NT with mulch compared to NT without mulch. Furthermore, mulching under both no-tillage and conventional tillage in a silty clay loam soil significantly increased root length and rooting density of crops owing to the evident improvements in soil water, temperature and bulk density. Acharya and Bhagat (1984) reported that pine needle mulch applied on conventionally cultivated plots resulted in much higher rooting density of maize at depths below 10 cm compared to that under no mulch (Plate 1). This was ascribed to moderation of the soil physical environment that also resulted in better drainage of water during heavy rains. In a sandy loam soil, application of wheat residue mulch resulted in a significant increase in root length density and root mass density of maize at 0–15 and 15–30-cm soil depth due to better availability of soil moisture and favorable soil temperatures under mulching (Chatterjee et al., 2017). Acharya et al. (1998) reported that there was a significant increase in the root mass density of rainfed wheat under minimum tillage and lantana mulch that moderated the hydrological and thermal regimes compared to repeated conventional tillage in a maize–wheat cropping system. Thus, during prolonged dry spells the deeper roots may extract water stored in the lower layers of the soil profile and would help in mitigating the adverse effect of prolonged drought on crop growth.

Table 5 Effect of tillage and nitrogen on root growth and grain yield of rainfed wheat (*Triticum aestivum* L.) in a silty-clay loam soil (Typic Hapludalf).

Mulch Tillage (T)	Nitrogen	Root mass density (kg m ⁻³)		Grain yield (Mg ha ⁻¹)

Improvement of input-use efficiencies

The favorable effects of mulching on crop growth and yields through an improved soil environment enhance both water- and nutrient-use efficiency. Increases in water availability in the upper layers because of a reduction in evaporation and runoff losses under mulches is one of the reasons for increased input-use efficiency. Furthermore, modification of the soil hydrological and thermal regimes under mulches favor root proliferation, which can tap water and nutrients from a larger soil volume, thus improving water- and nutrient-use efficiency. Mulching results in better coordination of demand and supply of water resulting in complete extraction of profile-stored water, which improves water-use efficiency. As the grain yield–water use relation is linear

within the domain of limited water supplies, any increase in water supply beyond a minimum threshold would be directly reflected in increased grain yield and water-use efficiency (WUE).

Higher soil water content, particularly in the initial stages of crop growth, results in greater total water use by the crop, leading to more plant growth and higher yields. Another factor contributing significantly to higher yield is more efficient use of growing season precipitation when the surface is covered with mulches. The final consequence of higher yields with relatively small increases in total water use is higher WUE with mulching compared to without mulching.

Application of pine needles from pine forests as mulch at the time of sowing of some tuber crops like potato (*Solanum tuberosum* L.) improves the yield and WUE and results in the saving of nitrogen fertilizer and irrigation water (Table 6) (Acharya and Kapur, 2001). Hence, within certain limits, mulches can act as a substitute for both irrigation water and nitrogen fertilizer.

With increased water availability under mulching, crop response to fertilizer increases, thereby, improving the fertilizer-use efficiency. Enrichment of soil with plant nutrients through organic mulching materials boosts crop production. Furthermore, mulching helps in moderating the soil's thermal regime, which has a profound influence on nutrient transformations in soil, root growth and nutrient uptake by crop plants, and enhances nutrient-use efficiency by crops. Chatterjee et al. (2017) reported that application of wheat residue mulch to a maize crop on a sandy loam soil resulted in significant increase in root length density, grain yield, and water- and nitrogen-use efficiency by maize.

In rainfed areas, sowing of crops, especially the winter crops in the post monsoon season, is delayed by late arrival of winter rains and hence the efficiency of water- and nutrient-use is low. Under such situations, the presence of soil surface cover in the form of an organic mulch compensates for the crop growth and grain yield compared to unmulched bare soil. Sharma and Acharya (2000) reported that the presence of *Lantana camara* L. mulch (retained over the surface after harvest of maize in the post monsoon season) and delayed sowing of rainfed wheat under no-tillage together with *Lantana camara* mulch after the late arrival of winter rain compensated more in terms of crop growth and grain yield than sowing rainfed wheat under conventional cultivation, but without mulch (as farmers practice).

Das et al. (2015) reported similar results of higher grain yield and thereby increased input-use efficiency from the north-east Indian Himalayan region with in-situ soil moisture conservation in a maize–toria (*Brassica campestris* L.) system using residues of the preceding rainy season maize crop and mulching with locally available weed biomass of common ragweed (*Ambrosia artemisiifolia* L.), applied before the sowing of toria. The productivity of toria was enhanced by about 99%, due only to the retention of maize stalk cover (MSC) as a mulch. Mulching with MSC + *Ambrosia* sp. (5 t ha^{-1}) + poultry manure (5 t ha^{-1}) recorded the highest seed yield for toria (four-year average: 641 kg ha^{-1}), which was 228 and 64% higher than no mulching (control) and MSC alone, respectively. MSC + *Ambrosia* mulch 10 t ha^{-1} gave the highest net returns and benefit: cost (B:C) ratio of the maize–toria system. The overall B:C ratios were better under zero tillage (ZT) than conventional tillage (CT). Similarly, in the same region, double mulching with in-situ maize stover mulch (MSM) + fresh biomass of white hoary pea (WHP-*Tephrosia candida* DC.) and MSM + fresh biomass of ragweed (RW0) showed improved soil moisture content, relative leaf water content of crops during the dry season, higher soil organic carbon (SOC) content and stocks at 0–15-cm depth, maximum soil microbial biomass carbon and dehydrogenase activity, and the highest system and water productivity than for no mulch (Ngangom et al., 2020).

Furthermore, the presence of mulch on the surface in conservation agriculture increased the average yield of wheat by 2–4% compared to conventional till wheat and saved in the cost of labor, fuel, chemicals, etc. It saved about 20 L of fuel per hectare due to sowing wheat in a single operation, increased nutrient-use efficiency by continuous recycling of residues over 3–4 years, and produced the same yield with 30–40 kg ha^{-1} less nitrogen use and significantly higher (10–15%) nutrient-use efficiency, produced more crop per drop of water through reduction in evaporation loss equivalent to about 45 mm (0.45 million liter) during the wheat season. It also reduced the risk of biotic and abiotic stresses, improved the environment by reduction in GHGs, reduced air pollution caused by rice crop residue burning, reduced terminal heat effects, as straw mulch lowered the canopy temperature in wheat which

helps in adapting to terminal heat, and resulted in a reduction in air pollution by PM_{2.5} and PM₁₀ particles, black carbon and noxious gases, by preventing burning of crop residues (NAAS, 2017).

Role of cover crops on soil quality improvement

Cover crops contribute to the improvement of soil quality through their decomposition by soil microbes. Their decomposition depends upon their nature, contact between soil and cover crop residue, soil moisture content and temperature, and microbial population. Decomposition of cover crops adds to the soil organic matter, which improves the soil physical condition and also contributes to the fertility status of soil. The degree of enrichment depends on the quantity and quality of cover-crop biomass.

Cellulose-rich plants or plant parts degrade far more rapidly than lignin-rich plants such as mature grasses. Leaf portions of the shoot system degrade far more rapidly than those of the stem. With decomposition, the resulting increases in SOM benefit the soil by improving its structure, thus enhancing gaseous exchange, internal drainage, nutrient exchange and water retention. Increased SOM leads to greater soil biodiversity, which is at the center of all SOM dynamics and increased aggregate stability which, in turn, means a reduced tendency to erode (Edwards and Burney, 2005).

From the standpoint of soil nutrient enrichment, cover crops contribute to the nutrient pool through the mineralization of decaying biomass under the influence of soil biota, which release the full range of plant nutrients in an available form. Where the decaying material is leguminous, nitrogen enrichment is predominant because of the low C/N ratio of this family of plants and, particularly, the capacity of their roots to fix atmospheric nitrogen in symbiotic association with bacteria. Thus, by root rupture or necrosis, the soil eventually benefits from this nitrogen-fixing activity. *Pueraria phaseoloides* L., a leguminous cover crop popular in the tropics, accumulated between 150 and 250 kg N ha⁻¹ within 4–18 months in parts of West Africa. The resulting nutrient enrichment of the soil following cover-crop fallows generally means an increase in crop production and savings on fertilizer costs, particularly where fertility is poor in areas such as Latin America and Africa. Tropical leguminous cover crops are also known for their foliar abundance. Some species contribute over 95% to total litter fall and are particularly favored in orchards and tree plantations if they are shade-tolerant and non-competitive (Edwards and Burney, 2005).

Role of cover crops on runoff and soil erosion control

Increased foliar mass of the cover crop reduces splash erosion with increasing ground coverage because of interception of the rainfall impact, which can be incorporated as a crop management factor in calculating soil loss. Cover crops work by reducing splash detachment and by intercepting the splashed soil, thus limiting its trajectory movement (Edwards and Burney, 2005). The effectiveness of cover crops in reducing soil erosion depends on its ground coverage, i.e., leaf area index and root structure. Parsons et al. (1994) reported that a comparison of cover-management effectiveness under varying degrees of canopy cover with a field rainfall simulator, showed that soil loss was not affected by a canopy of potatoes of up to 5%. A canopy of 70% was required before the crop cover could keep the soil reasonably in place, and a 90% canopy was needed before it was as effective as a mature stand of red clover (*Trifolium aestivum* L.) in the same study. Over longer distances, the progressive build-up of runoff generates an increasing shear stress on the soil surface. As the effects of runoff increase relative to the constant effects of splash downslope, the root structure of the cover crop becomes increasingly important for keeping the soil in place.

Recommendations and policy decisions on mulching and cover crops

Appropriate policy decisions may be taken for the wide adaptability of mulch and cover crop technology as suggested below.

- Proper research and development activities for site-specific conservation agriculture practices and mulching should be promoted.
- Awareness should be developed among farming communities about the importance of mulching, cover crops and conservation agriculture using field demonstration and extension services
- Legislation should be enacted to stop burning of crop residues by farmers. Some incentives to the farmers may be given to adopt conservation agriculture with minimum tillage and spreading of crop residues as a mulch rather than their burning.
- Practicing all three principles of conservation agriculture yields the desired benefits. Promoting conservation agricultural practice involving reduced tillage, residue retention and improved crop rotation including legumes, is a step toward sustainable agriculture that not only conserves water and favorably moderates physical, chemical and biological soil health and facilitates soil organic carbon sequestration, but also helps with greater nutrient-, water- and energy-use efficiency and minimizing soil erosion.
- Production of machinery and assured access by farmers to perform conservation operations including minimum till, seed and fertilizer placement etc. in one go. For small and marginal farmers, this machinery should be made available for hire.
- Growing short duration legumes in cereal based rotations should be promoted by giving some incentives to the farmers because it can act as a cover crop and improve soil health, and could provide pulses to meet the nutritional requirement of the world's growing population.

Conclusions

Mulching has a great potential for improving the soil's physical, chemical and biological health. This practice also helps in improving root and shoot growth, productivity and input-use efficiency. Further, this practice can improve environmental quality by enhancing soil organic carbon sequestration and reducing greenhouse gas emissions. However, this technology has some limitations. Appropriate policy decisions should be taken for addressing these limitations with the provision of technical and financial support to farmers. Together with mulching, short duration pulses could be promoted as cover crops in cereal based rotations to improve soil health, reduce soil erosion, and improve crop productivity and farmers' income. All three principles of conservation agriculture need to be followed to achieve the desired benefits. Site-specific mulching, cover cropping and conservation agricultural practices should be developed for sustainable climate-smart agriculture.

Abstract

Biochar is a pyrogenic carbonaceous material with well-developed porous structure and tunable functionality, and has triggered great interests in its agronomic and environmental benefits. However, unintended consequences related to biochar application are poorly understood. This chapter provides a systematic review on the structural development and characterization of biochar, which impact its function as a soil amendment including carbon sequestration, soil improvement, salinity and drought stress amelioration, and remediation of polluted soils. The relationships between biochar properties and its applications as well as the potential risks on plants and humans are also analyzed critically. Future research foci are suggested for green and sustainable applications of biochar.

Key points

- Feedstock and strategies for biochar production and modification are described.
- Effects of feedstock used and pyrolysis conditions on biochar's physicochemical properties are discussed.
- Agricultural and environmental benefits of biochar application to soils are reviewed.
- Potential ecological and human health risks associated with biochar application to soils are discussed.
- Future research outlooks are proposed.

Introduction

Biochar is a carbon-rich porous material produced from the thermal decomposition of raw biomass under an oxygen-limited atmosphere. Various biomass materials have been used for biochar production including agricultural, forestry, food and garden wastes, livestock carcasses and manure, sewage sludge, biosolids, and aquatic organisms such as micro- and macro-algae. The strategies for biochar production include slow and fast pyrolysis, hydrothermal carbonization, flash carbonization, gasification, and torrefaction (Fig. 1). Slow pyrolysis and hydrothermal carbonization are the most predominantly used methods for biochar production. Biochar is a heterogeneous mixture of an amorphous less-carbonized fraction and a microcrystalline graphitic structure. It is characterized by well-developed porosity, large specific surface area (SSA), and abundant oxygen-containing functional groups (OFGs) and minerals. Specific properties of biochar are mainly regulated by feedstock composition and heat treatment temperature (HTT) (Lehmann, 2007; Yang et al., 2021).

Biochar has gained increasing attention because of its potential agronomic and environmental benefits through carbon sequestration, enhancing soil productivity, alleviating salinity and drought stress, and immobilizing contaminants in soils. The recalcitrant nature of biochar's carbon structure and its strong adsorption capacity to CO₂, together with sustainable biochar

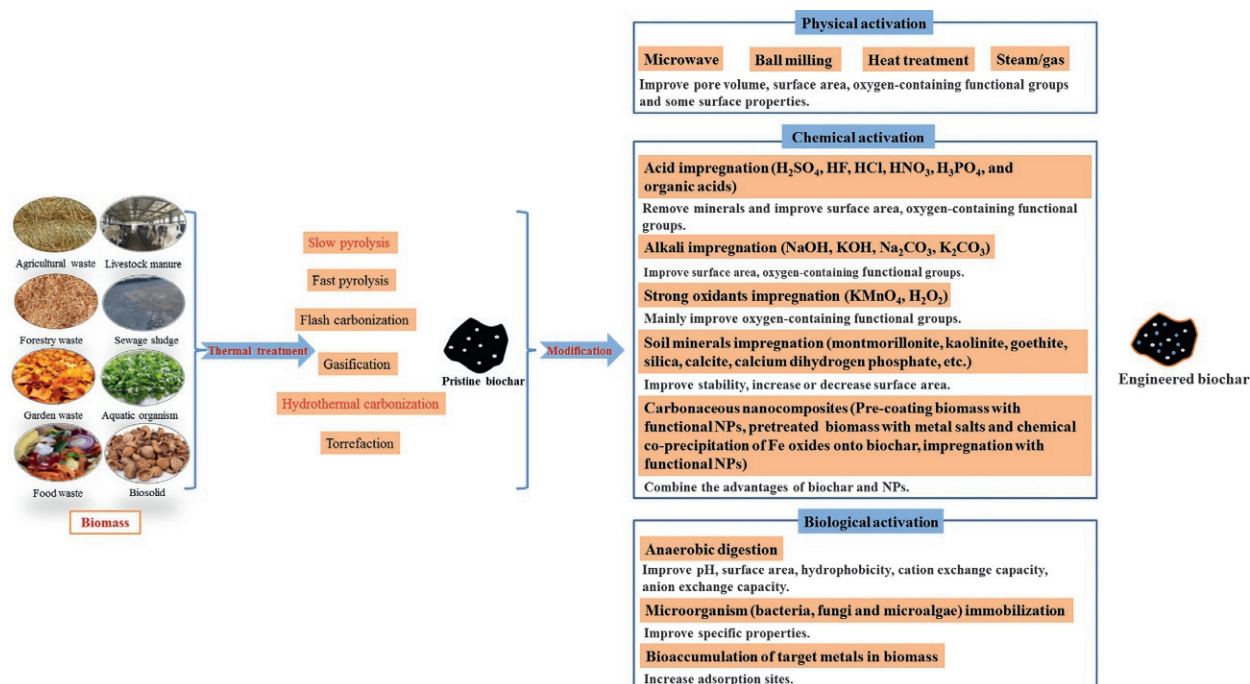

Fig. 1 Biochar production and modification.

production and soil application have the potential to enhance long-term carbon storage and remove carbon from the atmosphere, thereby mitigating climate change. Biochar also provides a potential route to increasing plant productivity and crop yields by improving soil quality and soil fertility levels. The improvement of soil quality and fertility after biochar incorporation into soil can also contribute to the alleviation of salinity and drought stress to plants. Finally, biochar's capability to immobilize harmful contaminants in soil makes it an effective material to improve food safety in areas of contaminated soils. However, biochar's functions as a soil amendment are greatly regulated by its physicochemical properties. Additionally, biochar aging in soils may cause considerable changes in its physicochemical properties, thereby affecting biochar's applications in agriculture and environment (Saifullah et al., 2018; Wang et al., 2020).

Although there are various agronomic and environmental benefits of biochar application to soil, potential risks related to ecological and human health are of great concern and need to be addressed before large-scale application in agricultural practices. It has been reported that some toxic substances inherent in biochar such as polycyclic aromatic hydrocarbons (PAHs) and heavy metals may be released into soils, having negative effects on soil biota. Persistent free radicals (PFRs) present in biochar that depend on feedstock and production conditions can induce the generation of reactive oxygen species (ROS), thus causing agro-environmental risks (Godlewska et al., 2021). Compared to the numerous studies outlining the multiple functions of biochar in agriculture and the environment, the potential risks of biochar application in soils have seldom been addressed.

The main objective of this chapter is to provide a balanced perspective on the beneficial effects and critical issues of biochar application to soil considering both the agricultural ecosystem and also wider environmental aspects. The aims of this chapter are to (i) analyze structural development and characterization of biochar in the context of heat treatment conditions; (ii) highlight potential agronomic and environmental benefits of biochar application to soil; and (iii) discuss potential unintended consequences. Future research outlooks are also put forward.

Typical properties of biochar

Heat treatment temperature (HTT)

Heat treatment temperature (HTT) is considered to be a dominant parameter influencing biochar properties. Broadly speaking, carbon and mineral contents, pH, alkalinity, aromaticity, surface area, porosity, and zeta potential increase with increasing HTT. While yield, albedo, cation exchange capacity (CEC), oxygen-containing functional groups (OFGs), nitrogen and sulfur contents, and aliphaticity/polarity decrease with increasing HTT. The hydrophobicity of biochar first increases, then decreases with increasing HTT (Fig. 2) (Xiao et al., 2018). The effect of HTT on biochar characteristics is attributed to the loss of volatile organic compounds (VOCs), nitrogen (N) and sulfur (S), and redistributions of its pore structure.

Fig. 2 Biochar property variations with increasing heat treatment temperatures.

Feedstock composition

The composition of biomass also plays an important role in biochar properties. Biomass (e.g., wood, pine, bamboo) with higher contents of lignin results in larger yields, carbon contents, fixed carbon content, greater surface area and porosity, and lower ash contents. Wet feedstock including livestock manure and sewage sludge derived biochar has higher ash and nutrient contents, CEC, pH and alkalinity, but a lower carbon content, surface area and porosity compared to biochar derived from dry feedstocks like agricultural, forestry and garden wastes. Moreover, wet feedstock-based biochar contains less fixed carbon compared with biochar produced from dry biomass (Lian and Xing, 2017; Nidheesh et al., 2021). Therefore, it is reasonable to speculate that dry biomass-based biochar with a large fixed carbon content are of high quality, especially in relation to long-term carbon storage which suggests it can contribute to climate change mitigation.

Residence time

Residence time is also a factor affecting biochar properties. Research indicates that the surface area and porosity initially increase, then decrease with increasing residence time. Sufficient reaction time accelerates the release of volatile matter and the development of pore structure. However, prolonged exposure to high temperatures may obliterate the pore structures of biochar. Increasing residence time may lead to an increase in fixed carbon content (Leng et al., 2021).

Rate of heating

The rate of heating also affects biochar's surface area and porosity. At first, an increase followed by a decrease in surface area and pore volume of biochar with an increase in rate of heating was proposed. Increasing the rate of heating accelerates heat and mass transfer, thus increasing surface area and total pore volume of biochar. However, an excessively high rate of heating may lead to the rapid diffusion of volatile matter, thus blocking the entrance of pore channels (Leng et al., 2021).

Biochar applications in agriculture and other environments

Climate change mitigation

Biochar has potential to mitigate climate change through carbon sequestration by storing carbon within the biochar itself and by capturing CO₂ from the atmosphere as well as by reducing CO₂ emissions. The abundant OFGs on the surface of biochar contribute to the adsorption of CO₂. Additionally, biochar application to soils reduces the content of labile C in soils, thus reducing CO₂ emissions from soils (Lehmann, 2007). Greenhouse gas (e.g., CH₄ and N₂O) emissions from soils may also be affected by

the application of biochar to soil. Inhibition of methanogenic archaeal activity, increase in the *pmoA* gene abundance and activity of methanotrophs, and decrease in the ratio of methanogenic to methanotrophs abundances have been found to be responsible for the reduction of CH₄ emissions from soil after biochar application. Of these processes the increased activity of methanotrophic proteobacteria and decreased ratio of methanogens to methanotrophs abundances are mostly responsible for the reduction of CH₄ emissions. The mechanisms responsible for the reduction in N₂O emissions mainly include: (i) biochar liming effect increases *nosZ* gene abundances, leading to an accelerated reduction of N₂O to N₂; (ii) biochar increases the adsorption of NO₃⁻ and/or NH₄⁺, decreasing the availability of inorganic nitrogen substrate for nitrification and denitrification; (iii) improves soil aeration and O₂ content, restraining the denitrification process; (iv) inhibits nitrification or denitrification processes by releasing toxic compounds such as PAHs into soils; and (v) increases the availability of dissolved organic carbon (DOC), leading to complete denitrification (Xiao et al., 2018; Yang et al., 2021).

Soil improvement

In agriculture, biochar can improve soil fertility by providing direct nutritional value and improving nutrient-use efficiency. Biochar can be used as a slow-release fertilizer by releasing inherent mineral fractions (e.g., N, phosphorus (P), potassium (K), calcium (Ca), magnesium (Mg)) into soils. The slow-releasing property of biochar is due to its unique structure. The porous network within biochar and the unique association of nutrient elements with the carbon matrix contribute to slow nutrient release. These properties also endow it with strong sorption capacity for nutrients, enabling their concentration followed by slow desorption into soil (Hagemann et al., 2017; Xiao et al., 2018). The loading of metallic (oxyhydr)oxide nanoparticles (NPs) on biochar increased the sorption performance for phosphate and other nutrient elements. Therefore, the metallic (oxyhydr)oxide-biochar nanocomposites have great potential in recycling nutrients from wastewater and holding them in the soil as a fertilizer for a long time (Yao et al., 2013). The feedstock composition plays a crucial role in determining biochar's contents and species of elemental fertilizers. For example, straw-derived biochar contains abundant silicon; soybean (*Glycine max* (L.) Merrill) root-derived biochar is characterized by a rich N fraction; eggshell yields biochar containing a large amount of calcium; sewage sludge-based biochar has abundant phosphate and other minerals. These various attributes of biochar result in its potential use as slow-release fertilizers. Moreover, HTT, soil properties and nutrient element species have a significant influence on the characteristics of biochar fertilizer release. It was reported that N became less available with increasing HTT by transforming N from NH₄⁺ to heterocyclic-N. Low soil pH contributed to the release of N, P and K, while it suppressed the release of dissolved silicon (Si) from biochar. Silicic acid was more available to plants than crystal silicon within biochar (Wang et al., 2019; Xiao et al., 2018).

Biochar also has positive effects on improving soil quality by improving microaggregation and soil structure as well as by increasing soil water holding capacity. The appropriate application of biochar with high ash contents is recommended for improving the quality of acidic soil by increasing the soil pH and ameliorating Al toxicity. The mechanisms for alleviating soil Al toxicity by biochar are delivered through its strong alkalinity and its high sorption capacity to Al (Qian et al., 2013). Furthermore, application of biochar to soil can stimulate microbial biomass and improve microbial community structure by providing bioavailable carbon sources, which indirectly could also improve soil quality. Also, the beneficial rhizosphere environment for microbiota and earthworm populations induced by biochar amendment may result in improved plant growth. On the other hand, biochar application can suppress soil pathogens by triggering beneficial microbial activities, thereby enhancing plant growth.

Salinity and drought stress amelioration

Salinity and drought are major abiotic stresses that limit crop productivity worldwide. Application of biochar has promise for improving soil properties and plant growth in salt-affected soils. Acidic biochar application to salt-affected soils has been shown to be effective in improving soil physical (e.g., porosity, water holding capacity, bulk density, and soil aggregation), chemical (e.g., electrical conductivity, pH, and exchangeable sodium percentage), and biological (e.g., diversity and growth of soil organisms) properties. Laboratory and field studies have shown that acidic biochar application to salt-affected soils alleviated salinity stress on plants and improved plant growth through the direct release of essential macronutrients (e.g., N, K, P) and micronutrients (e.g., copper (Cu), zinc (Zn), iron (Fe), and manganese (Mn)), which offset nutrient deficiency. Indirect benefits from biochar application to salt-affected soils on the improvement in crop productivity include: (i) improved soil physical, chemical, and biological properties; (ii) reduced bioavailability of Na due to its adsorption on biochar; (iii) reduced oxidation stress by decreasing malonaldehyde (MDA), O₂•⁻, and hydrogen peroxide (H₂O₂) contents; (iv) reduced osmotic stress by increasing water-use efficiency; (v) improved stomatal conductance, and photosynthesis efficiency; (vi) enhanced seed germination; (vii) lowered levels of phytohormone production; and (viii) the stimulation of microbial activities (Saifullah et al., 2018). Biochar in conjunction with other materials such as chemical soil amendments, nutrients, and microbes proved to be superior in promoting plant growth and productivity under salt stress compared to biochar alone (Saifullah et al., 2018).

Ammonia (NH₃) volatilization is a major concern in salt-affected soils. The pore structure, large surface area, and abundant OFGs of biochar play an important role in ammonium (NH₄⁺) retention through surface adsorption and ion exchange to NH₄⁺. Reduction of NH₃ volatilization could increase nitrogen-use efficiency in salt-affected soils amended with biochar. It should be noted that a large application of alkaline biochar may facilitate NH₃ volatilization in salt-affected soils resulting from the competitive adsorption between NH₃/NH₄⁺ and salt ions and aggravated inhibition of nitrification (Zhu et al., 2020).

Biochar application was also proposed to mitigate drought stress. It improves water-use efficiency through enhancing the rate of photosynthesis and plant growth. Xylem water potential, stomatal conductance and chlorophyll content are also enhanced.

Additionally, biochar plays an active role in osmoregulation, resulting in reduced sodium (Na) uptake and increased K uptake. Combining biochar with other materials (e.g., silicon (Si) nutrition and plant growth promoting rhizobacteria) had greater positive effects on plant growth under drought stress than the sole application of biochar (Mansoor et al., 2021).

Immobilization of toxic metals

Biochar has diverse influences on the immobilization of toxic metals in soils. Numerous laboratory or field studies on biochar application for the immobilization of cationic heavy metals (e.g., lead Pb(II), cadmium Cd(II), Cu(II), Zn(II), and mercury Hg(II)) in soils have shown promising results. Biochar can immobilize and reduce the bioavailability of metal cations through several mechanisms including cation exchange, electrostatic attraction, surface and inner-sphere complexation, cation- π interaction, and precipitation (Fig. 3) (Ahmad et al., 2014). The abundant OFGs (e.g., hydroxyl, carbonyl, and phenolic groups) on biochar occur mainly in dissociated forms and can be deprotonated at a certain range of pH values, favoring the cation exchange, electrostatic attraction and surface complexation between biochar and metal cations. The abundant alkali and alkaline earth metallic species in biochar also participate in cation exchange with cationic heavy metals. The mineral oxides (e.g., ferric oxide (Fe_2O_3) particles, and manganese oxide (MnO_x) particles) and organic carbon in biochar are responsible for the inner-sphere complexation with cationic metals. The aromatic structure of biochar promotes the cation- π interaction. In addition, co(precipitation) of cationic metals with biochar's inorganic phases containing carbonate, silicate, and phosphate was also widely reported. Biochar-induced precipitates such as hydrocerussite ($\text{Pb}_3(\text{CO}_3)_2(\text{OH})_2$), lead hydroxypyromorphite ($\text{Pb}_5(\text{PO}_4)_3\text{OH}$), azurite ($\text{Cu}_3(\text{CO}_3)_2(\text{OH})_2$), zinc silicate (Zn_2SiO_4), zinc hydroxide ($\text{Zn}(\text{OH})_2$), cadmium carbonate (CdCO_3), and cadmium phosphate ($\text{Cd}_3(\text{PO}_4)_2$) are relatively stable and have a low bioavailability in soils (Wu et al., 2020). The relative contribution of these mechanisms in the immobilization of metals by biochar varies among metal cations. Several studies have reported that cation exchange and surface complexation with OFGs were the predominant mechanisms for the immobilization of Cd(II) and Pb(II). However, other studies have reported that surface complexation and precipitation dominated the sorption of Pb(II). Notably, HTT has been shown to influence the mechanism through which biochar immobilizes metal cations in soils. Despite different contributions of various immobilization mechanisms, some general trends can be identified: (i) cation exchange and surface complexation with OFGs are the dominant mechanisms for cationic metals sorption by biochar produced under low HTTs; whereas, with increasing HTTs the contributions of these mechanisms are superseded by other processes including cation- π interaction and precipitation due to the decrease of OFGs and formation of graphitic structures; (ii) the inorganic phases of biochar, especially if derived from livestock manure and sewage sludge rich in minerals, play an important role in the immobilization of cationic metals through precipitation (Wu et al., 2020). An increase in soil pH induced by the application of biochar (i.e., liming effect) can also accelerate the precipitation and adsorption of cationic metals on soil particles, indirectly enhancing the immobilization of cationic metals. However, an increase in Cu(II) mobility in soils amended with biochar was reported in several studies, which was associated with increased dissolved organic C (DOC) forming soluble Cu-DOC complexes. The discrepancy between Cu(II) activation and immobilization was mainly due to the different contents of biochar DOC. Generally, the DOC contents are relatively high for relatively low-temperature biochar (<500 °C), which has negative effects on the retention of Cu(II) in soils by the formation of soluble Cu-DOC complexes. On the

Fig. 3 Schematic diagram showing the various mechanisms of biochar for the immobilization of cationic metals.

other hand, the blocking of biochar pores by DOC prevents physical adsorption of Cu(II). For high-temperature biochar ($>600^{\circ}\text{C}$), DOC is generally deficient, and processes such as electrostatic attraction, cation- π interaction and precipitation can offset the role of DOC in Cu(II) mobilization (Ahmad et al., 2014).

Purposive tailoring of the physicochemical properties of biochar can greatly enhance its effectiveness in the immobilization of heavy metal(loid)s in soils. Biochar tailoring can be achieved by physical, chemical, and biological modifications. Chemical modification, especially involving metal salts or metal oxides has been widely used to reduce the mobility, availability, and toxicity of cationic metals in soils. The attachment of metal oxide NPs on the surface of biochar can not only increase the number of effective active sites but also the electrostatic potential, favoring the immobilization of cationic metals in soils (Wu et al., 2020). In addition to the modification of metal salts or metal oxides mentioned above, heteroatom modification was also found to be effective in improving the sorption capacity for cationic metals. For example, phosphorus-modified biochar effectively reduced Cd(II) and Pb(II) bioavailability by forming precipitates with low solubility such as cadmium hydroxylapatite ($\text{Cd}_5(\text{PO}_4)_3\text{OH}$), $\text{Cd}_3(\text{PO}_4)_2$, pyromorphite ($\text{Pb}_5(\text{PO}_4)_3\text{Cl}$), lead phosphate ($\text{Pb}_3(\text{PO}_4)_2$), and $\text{Pb}_5(\text{PO}_4)_3\text{OH}$. Sulfur modified biochar was also found to reduce Cd, Cu and Hg(II) bio-accessibility remarkably by forming stable sulfide precipitates (Wang and Wang, 2019).

Biological modification associated with microbial immobilization technology has created broad interest in toxic metal immobilization. Metal-resistant microorganism-biochar immobilized complexes can directly or indirectly remediate soils contaminated with cationic metals. The addition of the cationic metal-tolerant strain *Pseudomonas* sp. NT-2 immobilized on biochar enhanced the stability of Cd(II) and Cu(II) by increasing the fraction of residual Cd(II) and Cu(II) as well as by reducing the fraction of exchangeable and carbonate bound Cd(II) and Cu(II) in soil. The synergistic effects were attributed to surface complexation with OFGs and precipitation on biochar as well as the surface complexation with abundant functional groups (e.g., carboxyl, hydroxyl, amine, phosphate) on microbial cells. The application of phosphate solubilizing bacteria immobilized on biochar significantly enhanced the stabilization of Pb(II) in soil by forming stable precipitates such as $\text{Pb}_5(\text{PO}_4)_3\text{OH}$ and hydroxylpyromorphite ($\text{Pb}_{10}(\text{PO}_4)_6(\text{OH})_2$). Biochar-based microbial immobilization technology as a bio-augmentation method has also shown promising results for indirect remediation of soils contaminated with cationic metals. Inoculation of cationic metal-resistant bacteria or plant growth promoting bacteria immobilized on biochar improved the phytoextraction efficiency of cationic metals by promoting plant growth and metal accumulation in plants (Wu et al., 2021).

Biochar aging in soil may have diverse effects on metal immobilization performance. Biochar contains more OFGs after oxidation by chemical and biological processes in soils, and tends to adsorb greater amounts of metals due to enhanced surface complexation with OFGs. Nevertheless, the loss of inorganic minerals and the blockage of biochar pores are thought to diminish biochar sorption capacities for cationic metals. Overall, the long-term effectiveness of biochar in the stabilization of cationic metals gradually weakened in long-term field trials (Wang et al., 2020).

For metal anions (mainly arsenic (As) and chromium (Cr)), biochar also presents great potential in the remediation of As and Cr contaminated soils. The species of As and Cr are sensitive to soil conditions such as redox potential and soil pH. It has been demonstrated that biochar produced from sewage sludge had a high As(V) immobilization capacity in soil, mainly due to the inner-sphere complexation of As(V) with large contents of Fe_2O_3 in biochar. Immobilization of As(III) in paddy soils can be achieved by the adsorption of As(III) on biochar through electrostatic attraction and surface complexation which oxidizes As(III) to the less mobile As(V). However, pristine biochar also showed conflicting behavior in the immobilization of As in paddy soils. It was found that As mobility increased in soils treated with biochar. This may be attributed to the increase in soil pH and the competition of As with soluble P in biochar (Ahmad et al., 2014). Biochar addition also increased the abundance of genes such as *arrA* and *arsC*, which were associated with the reduction of As(V) to mobile As(III) species. These contrasting outcomes may be related to different properties of biochar and soil (Kumarathilaka et al., 2019). The use of modified biochar is, therefore, effective in immobilizing As in paddy soils and reducing As accumulation in rice grains. It has been reported that biochar loaded with Fe or Mn oxide NPs greatly improved As(III) and As(V) removal kinetics and capacity. Both the redox transformation of As(III) to less mobile As(V) species and the adsorption of As(III) and As(V) on biochar increased after loading with Fe or Mn oxide NPs (Kumarathilaka et al., 2019). Studies have clearly demonstrated that Si application to soil could reduce As accumulation in rice tissues, which is attributed to reduced As uptake and increased Si uptake by Si uptake transporters. Therefore, biochar rich in Si derived from wheat and rice straw can be used to reduce As uptake to rice tissues. The main mechanisms responsible for Cr(VI) sorption on biochar are assumed to be the adsorption of Cr(VI) on the surface of biochar by electrostatic interactions between the Cr(VI) anion and the positively charged functional groups and the subsequent reduction to Cr(III). The Cr(III) was more tightly immobilized on biochar through surface complexation and precipitation. Sugarcane bagasse-derived biochar showed greater immobilization capacity of Cr(VI) in soils due to its lower pH compared with straw-derived biochar. Low-temperature ($<500^{\circ}\text{C}$) biochar was beneficial for the retention of Cr(VI) in soils because of the large contents of OFGs in biochar, which were responsible for the reduction of Cr(VI) to Cr(III). Biochar modification with nZVI effectively facilitated the immobilization of Cr(VI) by enhancing the reduction of Cr(VI) to Cr(III). An immobilization efficiency of Cr(VI) of 100% could be achieved by the addition of 0.8% biochar-nZVI nanocomposites to Cr contaminated soil (Zheng et al., 2021).

Removal of organic pollutants

Biochar has shown strong affinity to many organic pollutants in contaminated soils, thereby reducing their detrimental effects on plants. Adsorption and partitioning are the common mechanisms controlling the bioavailability of organic pollutants in soils. Adsorption is a non-linear and competitive process; whereas partitioning represents the opposite process. Adsorption mechanisms include H-bond, π - π electron donor-acceptor interaction (π - π EDA), hydrophobic effect, pore-filling, and electrostatic attraction.

Sorption mechanisms of hydrophobic organic compounds (HOCs) evolved from partition-dominant at low HTTs to adsorption-dominant at high HTTs due to an increase in hydrophobicity and porosity of biochar. The contributions of H-bond and partitioning decreased; whereas the contributions of hydrophobic effect, π - π EDA, and pore filling increased with increasing HTTs because of the thermal structural transition of biochar. The nature of HOCs also affected the sorption capacities of biochar. It was found that the sorption of polar organic compounds such as phthalates (PAEs) was dominated by the adsorption process (π - π EDA, hydrophobic interactions, pore-filling); whereas the sorption of nonpolar compounds such as PAHs was mainly controlled by partitioning.

The sorption behavior of ionizable organic compounds (IOCs) is different from that of HOCs. The mechanisms responsible for the sorption of IOCs mainly included electrostatic attraction, π - π EDA, and H-bond. The sorption of IOCs depended strongly on soil pH and zero point of charge of biochar (pH_{zpc}). When soil pH < pH_{zpc} of biochar, biochar with net positive charges on its surface is suitable for the sorption of anionic pesticides. On the contrary, biochar is negatively charged at soil pH > pH_{zpc} of biochar and this promotes the sorption of cationic pesticides (Lian and Xing, 2017).

Biochar aging in soils may have diverse influences on the sorption capacities of organic pollutant. Natural aging of biochar produced under low HTTs can introduce more OFGs on the surface of biochar, contributing to π - π EDA and thus a substantial increase in the sorption capacities of organic pollutants. On the other hand, the introduction of OFGs during biochar aging may lead to the formation of water clusters, inhibiting the approach of organic pollutants to the biochar surface. Moreover, the blockage of biochar pores can cause a decrease in physical adsorption of organic contaminants (Wang et al., 2020).

Degradation is another important removal pathway for organic pollutants from soils. In-situ remediation of soils through advanced oxidation processes (AOPs) were highly-effective in the complete removal of organic pollutants from soils. A recent study found that degradation efficiency of bisphenol A in soil of 99% could be achieved by the biochar-activated persulfate (PS) oxidation process. The persistent free radicals (PFRs) such as oxygen-centered and semiquinone-type free radicals in biochar could activate PS to generate the hydroxyl radical ($HO\bullet$) and sulfate radical ($SO_4^{\bullet-}$), which were responsible for the degradation of bisphenol A (Liu et al., 2020). Biochar loaded with spinel ferrite, Fe oxide NPs, and nZVI showed superior performance in activating PS and H_2O_2 to generate $HO\bullet$ and $SO_4^{\bullet-}$ to degrade organic pollutants in soils than pristine biochar. The Fe^{2+} in spinel ferrite- and Fe oxide NPs-supported biochar could serve as an effective activator for PS or H_2O_2 to produce $SO_4^{\bullet-}$ and $HO\bullet$. The nZVI on biochar could activate PS directly to generate $SO_4^{\bullet-}$. The Fe^{2+} or amorphous Fe(II) generated during the activation process could also induce PS to form $SO_4^{\bullet-}$. The contributions of $HO\bullet$ and $SO_4^{\bullet-}$ in the degradation of organic contaminants were different. For example, several studies found that $SO_4^{\bullet-}$ was the predominant reactive oxygen species (ROS) in the degradation of decabromodiphenyl ether in acid and neutral soil conditions. Other studies reported that both $HO\bullet$ and $SO_4^{\bullet-}$ were involved in the degradation of *o*-nitrochlorobenzene, while $SO_4^{\bullet-}$ played a more important role. Understanding of the heterogeneous activation processes and degradation mechanisms contributes to the development of AOPs.

Biodegradation is considered to be an eco-friendly and sustainable method for removing organic contaminants from soils. Biochar addition into soils stimulates the microbial degradation of organic contaminants by increasing the abundance of organic pollutant-degraders. It has been reported that the relative abundance of main PAH-degraders (e.g., *Azospirillum*, *Pseudomonas*, *Magnetospirillum* and *Bacillus*) increased in soils amended with biochar pyrolyzed at high temperatures (500–700 °C) (Ding et al., 2021). It is important to note that biochar aging in soils may favor the biodegradation of organic pollutants. An increase in OFGs after aging would promote biochar as an electron shuttle between colonized organic pollutant-degraders on the external and internal surfaces of biochar and organic pollutants (Wang et al., 2020). More importantly, the immobilization of organic pollutant-degraders with biochar as a carrier has greater potential in the biodegradation of organic pollutants than free microbes. Biochar exhibits well-developed porosity, large surface area, considerable mechanical strength, and tunable surface functionality, which are suitable for the attachment and growth of organic pollutant-degraders. Moreover, immobilized cells have greater resistance and adaptability to disturbance in the soil environment than free cells (Wu et al., 2021). Several studies suggested that petroleum hydrocarbons (PHCs)-degrading bacteria immobilized on biochar were effective in the bioremediation of soils contaminated with PHCs. The immobilized cells played a significant role in shorting the half-lives of PHCs and enhancing their biodegradation in soils. The immobilized cells were also efficient in the long-term degradation of PHCs in soils. The addition of other organic pollutant-degraders such as polyacrylamide-degrading bacteria (*Klebsiella* sp.), PAH-degrading bacteria (*Pseudomonas* sp. SDR4 and *M. alpina* JDR7), tebuconazole-degrading bacteria (*Alcaligenes faecalis* WZ-2), and methylene blue-degrading bacterial consortium immobilized on biochar is an attractive and efficient approach for the remediation of soils contaminated by organic pollutants by combining the advantages of highly efficient sorption of biochar and microbial degradation (Fig. 4) (Wu et al., 2021).

It is noteworthy that microbial degradation of organic pollutants is time-consuming and the reaction time for complete degradation is much longer than AOPs. Selecting suitable fast-growing organic pollutant-degrading bacteria is feasible to enhance the biological activity and efficiency of microbial degradation of immobilized cells (Wu et al., 2021). Additionally, insufficient mineralization of organic contaminants usually generated more recalcitrant or toxic intermediate metabolites, which could be toxic to soil biota (Yu et al., 2020). However, chemical degradation also has its limitations such as high energy input, large operational costs, and secondary pollution through the chemicals added. A high degradation efficiency and economic promise may be achieved by coupling microbial degradation with advanced oxidation processes, which should be further developed and evaluated.

Unintended consequences

Although biochar application may have agronomic and environmental benefits, its potential ecological and human health risks have to be considered. It has been reported that some biochars have several harmful substances including PAHs, polychlorinated

Fig. 4 The removal mechanisms of organic pollutants by cells immobilized on biochar.

Fig. 5 Potential risks associated with biochar application to soils.

dibenzo-p-dioxins and -furans (PCDD/Fs), volatile organic compounds (VOCs), PFRs, heavy metals, and water-soluble organic compounds (WSOCs) (Fig. 5) (Godlewska et al., 2021). The toxic effects of these harmful substances are related to their bioavailable fraction, which is mainly determined by the feedstock used, HTT and method of biochar production. For example, PAHs are formed during incomplete combustion of biomass. Research suggested that biochar produced by slow pyrolysis contained less PAHs than biochar produced by fast pyrolysis. The bioavailable PAH contents in biochar also vary with feedstocks used. It is suggested that *Miscanthus*-derived biochar has higher contents of PAHs than other biomass-derived biochar. Larger amounts of bioavailable PAHs were often found in medium- temperature biochar (400–600 °C). In general, the bioavailable fraction of PAHs is relatively small for the majority of biochar. The PCDD/Fs form mainly on the biochar surface during thermal decomposition of feedstock containing abundant chlorine, such as food waste. Low HTTs (200–400 °C) and short duration time (<120 min) favor the formation of PCDD/Fs on the biochar surface. It is estimated that PCDD/Fs always exist in insignificant quantities in biochar and pose a rather marginal risk to organisms. However, the repeated application of biochar may increase the ecological risk of PCDD/Fs. The VOCs are formed on the biochar surface or inside biochar pores by thermochemical transformations of biomass. The contents of VOCs in biochar decrease with increasing HTTs. A number of studies have reported that stable and large molecular PFRs are formed in biochar during the carbonization process. It was found that the electron paramagnetic resonance (EPR) signals in lignin-derived biochar were higher than that in cellulose-derived biochar. The EPR signals increased with increasing HTT for the

majority of biochar (Liao et al., 2014). Besides organic compounds, heavy metals (e.g., Cd(II), Cu(II), and Pb(II)) in biochar are of great concerns because of their toxicity. Heavy metal contaminants mainly originate from feedstocks rich in heavy metals, especially sewage sludge, animal manure, and plants grown on heavy metal-contaminated soils. The conversion of biomass with abundant heavy metals to biochar is considered a promising method for safe disposal of the biomass as well as significantly reducing the bioavailability and leaching of heavy metals. The contents of certain heavy metals increased with increasing HTTs, which may be attributed mainly to a 'concentration effect' resulting from the decrease in biochar yield. The bioavailability of heavy metals depends on heavy metal contents in raw biomass as well as the transformation and dissolution of heavy metals in biochar (Godlewska et al., 2021). The release of water-soluble organic compounds (WSOCs) from hydrochar was greater than that from biochar. With increasing HTT, the contents of phenols and organic acids in WSOCs increased (Hao et al., 2018).

Despite ecologically acceptable concentrations of these harmful substances in most biochar, it may pose an ecological risk to soil biota. For example, research reported that some contaminants (e.g., PAHs, cresols, methylated phenols) accumulated in biochar could be toxic to soil microorganisms. The PFRs in biochar might inhibit germination, damage plasma membrane, and retard plant growth. Other studies confirmed that PAHs in biochar can increase mortality and hamper the reproduction of soil invertebrates. Biochar-related dust emissions may have potentially adverse impacts on human health when applied to agricultural soils. The potential ecotoxicity of nano-sized biochar after ball milling was higher than that of pristine biochar due to its nanotoxicity. Except for the ecological risk directly induced by harmful substances in biochar, the changes in soil physicochemical properties after biochar addition may indirectly cause ecotoxicity to soil organisms. Increased soil pH after biochar incorporation may have a toxic effect on the reproduction of earthworms. Biochar's strong adsorption capacity for nutrients and thus their reduced bioavailability may have negative impacts on plant growth. Similarly, the strong water retention capacity of biochar may decrease the accessibility of water to plants (Fig. 5). It should be noted that low rates of biochar application may not have negative effects on soil biota, but application of biochar at excessively large rates is likely to generate unintended consequences.

Conclusions and perspectives

In this chapter, the agricultural and environmental implications of biochar application to soils are discussed. Numerous studies have demonstrated the great potential of biochar in various agricultural and environmental applications including climate change mitigation, soil improvement, the amelioration of salinity and drought stress, and remediation of polluted soils. However, potentially negative implications, and ecological and human health risks related to biochar application should not be overlooked before its large-scale application in agricultural and environmental practices. Further research is needed to enhance the potential agricultural and environmental benefits of biochar may include:

- (i) Considering the variety of feedstock used and pyrolysis conditions, biochar properties are highly variable. Differences in biochar properties affect its functions as a soil amendment as well as its environmental risks. Further research is needed to combine several methods to understand the charring mechanisms more precisely and to predict the resulting biochar properties. This would be useful to produce biochar with properties that would be suitable as a soil amendment and with little risk of releasing harmful substances.
- (ii) Owing to the excellent performance of tailored engineered/modified biochar, it has been widely used to enhance remediation efficiency of contaminants in soils. However, its potential and the unintended ecotoxicological consequences are seldom addressed. The potential toxicities of metal oxide NPs (e.g., ZnO, Fe₃O₄, TiO₂ NPs) to soil organisms have been elucidated in previous studies. The loading of metal oxide NPs on biochar may be ecotoxic to soil biota. Moreover, the leaching of metal ions from biochar-metal oxide nanocomposites may also lead to ecotoxicity of soil biota. It has been reported that the application of biochar-embedded nZVI could inhibit the growth of soil microorganisms. Therefore, it is necessary to monitor and assess the potential risk related to the application of engineered biochar.
- (iii) The long-term effects of biochar on the stabilization and bioavailability of contaminants, herbicides, pesticides, and nutrients in soils should be explored further. The changes in biochar physicochemical properties and soil conditions over time are likely to influence sorption and desorption kinetics of contaminants, thereby affecting the fate of contaminants in soils. For example, the increase in dissolved organic matter (DOM) induced by biochar aging may accelerate the activation of As (III, V) and Cu(II) in soils. Decrease in the long-term stabilization performance of biochar in soil may lead to the release of heavy metals sorbed to biochar. The long-term aging of biochar in soils can pose positive or negative effects on nutrient-use efficiency. Thus, long-term field experiments should be conducted to examine the aging effect on biochar's efficacy as a soil amendment.
- (iv) Although biochar can reduce bioavailability of contaminants and thus reduce their uptake by crops, its application would increase production costs, thus, little public acceptance is expected. To maximize the remediation benefits of biochar, more work is needed to identify the rates of application of biochar that achieve the remediation purpose as well as minimize input costs. Additionally, combining applications of biochar with other remediation technologies such as microbial remediation and cultivating low-metal accumulation crop cultivars could reduce input costs. Furthermore, biochar as a carrier for nutrients, moisture, pesticides and beneficial microorganisms such as N-fixing rhizobium bacteria could be attractive options and promote field application of biochar products.

Abstract

Carbon management in soils has a great potential both for climate change mitigation and adaptation. Mitigation can be achieved directly by the sequestration of carbon in the soil. Further carbon is usually added in the form of organic matter. As organic matter is a key factor of soil fertility and health, carbon management indirectly contributes to climate change mitigation by fostering ecosystem services that have the potential to reduce the need for external inputs and technical interventions in land management. Moreover, improving ecosystem services enhances the resilience and adaption of land-use in a changing climate.

Key points

- Carbon management in soils has a large potential for both climate change mitigation and adaptation.
- Carbon management in soils is based on the supply of soils with organic matter (and biochar), and or on the control of microbial turnover.
- Carbon management contributes directly to climate change mitigation by stabilizing carbon on mineral surfaces and within soil aggregates and micropores.
- Carbon management indirectly contributes to climate change mitigation by fostering ecosystem services that have the potential to reduce the need for external inputs and technical interventions, which in turn reduces industrial emissions and fuel consumption.
- Ecosystem services related to carbon management further improve the resilience and adaptiveness of land-use systems in a changing climate.
- Carbon sequestration in soils is a dynamic process, where different carbon fractions have different turnover times. Carbon may be stabilized in soils for a long time, but there is no permanent sequestration.
- Carbon sequestration in soils does not discharge other sectors from the responsibility to phase out fossil carbon emissions in the near future.

Introduction

Throughout the history of arable farming it has been acknowledged that organic matter supply to soil is a prerequisite for the development of fertile soils. In Europe, the 1st century Roman agronomist Columella stated that it is necessary to supply arable soils with organic matter, as the export of crop products creates an imbalance between inputs and outputs of organic matter on the field scale (Columella: *De re rustica libri duodecim*). Later, Albrecht Daniel Thaer developed a table to calculate the demand of different crops for organic manure (Thaer: *Grundsätze der rationellen Landwirthschaft*, vol.2). And Justus von Liebig, better known for the mineral nutrient theory and law of the minimum, stressed that organic matter supply is invaluable to maintain soil fertility (Liebig: *Chemische Briefe*). Awareness for the need to supply soils with organic matter was not only a European perspective, but is a characteristic of traditional arable societies throughout the world. A famous example is the formation of Terra Preta soils in the Amazonas by the build-up of organic matter to improve the fertility of pedogenetically poor tropical soils.

The aim of supplying soils with organic matter has always been to improve soil fertility, or -to be concise- soil functions in arable crop production. Carbon sequestration has only recently become an aim of soil organic matter (SOM) management to mitigate climate change.

Carbon sequestration—Potential and constraints

The idea of carbon sequestration is to capture atmospheric carbon and store it in soils. Soils comprise the second-largest carbon pool in the world (after oceans). Carbon in soils is either carbonate in soil minerals, or carbon in organic matter. Of these two, the organic matter pool is dynamic and can be increased (or decreased) by soil management. Carbon sequestration strategies therefore aim to increase organic carbon in soils.

According to Lal et al. (2018), carbon (C) sequestration in soils could achieve a C gain of 333 Pg by the end of this century, corresponding to a decrease of the atmospheric C concentration by 156 ppm. The “4 per 1000” initiative launched in 2015 at the United Nations Climate Change Conference in Paris claims that an annual increase of C levels in soils by 0.4% would offset approximately 30% of actual annual global C emissions for a yet undefined timespan until C saturation in soils has been reached (Minasny et al., 2017). Thus, the potential of soils in mitigating climate change is, in principle, considerable.

It must be considered, though, that both the calculation of Lal et al. (2018) and the “4 per 1000” concept refer to best-case scenarios that would require huge efforts in land management on a global level. Even though the annual rate of C sequestration proposed by the “4 per 1000” initiative may be feasible for many soils from a biophysical point of view, several barriers must be taken into account with regard to the implementation. Effective carbon sequestration in soils depends not only on technical and physical factors, but even more so on economic, social and political factors in human societies. These findings do not counteract the potential of soils to sequester carbon in principle, but they need to be taken into account in the public discussion, and in the development of cross-sector strategies for climate change mitigation.

Soil management for carbon sequestration not only contributes to climate change mitigation by capturing atmospheric carbon, but also supplies soils with organic matter which has an important effect on soil fertility and health. Recommended measures to increase soil carbon by management aim at increasing organic matter inputs, in particular by adapting crop rotations and cropping systems, and also the stability of added carbon in soils. The supply of soils with organic matter is a key factor for soil fertility and soil health, therefore, measures for carbon sequestration are synergistically connected to soil fertility management. Fertile soils, in turn, need fewer external inputs in the production systems, which contributes to decreasing greenhouse gas (GHG) emissions in the industrial sector. Therefore, production and climate change mitigation can be linked more easily in agriculture than in most other sectors.

Dynamics of organic carbon in soils

To utilize carbon management for climate change mitigation, it is necessary to recall the dynamics and functions of organic matter in soils.

The accumulation and depletion of organic matter in soils are basically biological processes. Apart from carbonate in mineral fertilizers and calcareous soils, the carbon in soils is of organic origin in living and dead organisms, and their turnover products. Organic matter in soils is continuously processed, and it is likely that there are no stable products at any stage of the turnover process, even though different materials may have different turnover times (Lehmann and Kleber, 2015). Carbon can be stored only temporarily in soils by incorporation into the living microbial biomass (short-term), or through physical protection from microbial breakdown by the soil structure or on mineral surfaces. Further, organic matter turnover is considerably decelerated under suboptimal turnover conditions, e.g. in wet soils, or, more generally, in subsoils.

Turnover of organic matter in soils

In the early soil organic matter models it was assumed that organic matter can be treated as one homogenous fraction. But over time, the limitations of this concept became more and more clear. Today, it is generally accepted that soil organic matter has to be subdivided into different pools with individual turnover times (Paul, 2016), where the mechanisms for stabilization were identified as (i) protection by incorporation in soil aggregates and (ii) protection on mineral surfaces. According to Marschner et al. (2008),

chemical recalcitrance is important mainly in the initial phase of organic matter turnover, while physical protection is the main mechanism in the long-term stabilization of organic matter in soils. Under suboptimal living conditions for microbes, biological activity and, correspondingly, the turnover of organic matter are strongly reduced in micropores and within aggregates. Therefore, clay-rich soils with tight aggregation and a large proportion of micropores have a greater potential to stabilize and sequester carbon than light soils with poorer aggregation.

Biological activity in soils depends on temperature, moisture and (with aerobic organisms) aeration. Extreme conditions (waterlogging, drought, low and high temperature) reduce microbial activity. Potential carbon sequestration, therefore, is greater under suboptimal conditions due to decreased turnover of organic matter. As a consequence, organic matter in the subsoil has longer turnover times than the same material in the topsoil, even if the material is not chemically recalcitrant and, in principal, accessible. Carbon inputs in subsoil, e.g., via plant roots, therefore play an important role with regard to carbon sequestration.

Essentially, we have to distinguish between the turnover of organic material that has been added to the soil by natural or technological sources, and the decomposition of SOM itself. While it is commonly assumed that soil microbes play the crucial role in this process, it has become increasingly obvious that the meso- and macro-fauna in soils also contribute considerably to organic matter turnover. This is partly due to the fact that faunal activities disintegrate and relocate litter thus creating new surfaces for improved decomposition. On the other hand, there are also changes in turnover intensity induced by bioturbation, especially by the activity of earthworms that improve aggregation with increased protection of organic matter.

Management impact on organic matter turnover

Soil texture, structure, temperature, moisture and aeration not only interact with each other, but also with management measures, in particular organic matter supply and tillage. The supply of soils with organic matter improves soil structure by fostering aggregation in light soils and by increasing the volume of meso- and macro-pores in heavy soils. Tillage disrupts soil aggregates, making occluded organic matter available for soil microbes. Therefore, both organic matter supply and tillage basically improve living conditions for soil microbes and thus increase biological activity. Provided that organic matter is supplied, this observation does not imply a reduction in carbon sequestration. Furthermore, the increase in microbial turnover will usually be overcompensated for by the addition of organic material itself and by growth of the microbial population. In addition, organic matter supply improves growth conditions for plants, leading to more biomass production and related residue inputs.

Tillage may also improve plant growth, which in turn increases biomass input with residues to the soil. Meta studies have shown that reducing tillage intensity has only a small positive effect on the amount of soil organic matter over the whole soil profile (e.g. Luo et al., 2010). Therefore, the proliferation of microbial activity by aggregate disruption should not be overrated.

Another important issue that has gained attention only recently are the stoichiometric implications of fertilizer additions for organic matter dynamics. As organic matter in soils has a comparatively narrow C:N ratio, it is clear that nitrogen is needed to retain organic carbon in the turnover process (Craine et al., 2007). Carbon-rich substrates with a wide C:N ratio have only a limited potential to increase soil organic matter, because a predominant share of the carbon will be lost in microbial turnover through respiration. In many cases, potential C retention during turnover is higher for organic material with a narrow C:N ratio than for organic material with a wide C:N ratio. This is true despite a faster turnover of N-rich material, if N is prevented from leaching by incorporation into the microbial biomass and organic turnover products. On the other hand, the application of N-rich fertilizers without significant coupled C input (synthetic N fertilizer, biogas liquid after slurry separation, dung water, etc.) may cause a priming effect in the turnover of native soil organic matter.

Carbon inputs

The conversion of atmospheric carbon into plant biomass is the only true C input in the soil-atmosphere carbon balance. All other organic matter amendments, such as compost and animal manure, re-distribute plant-derived carbon. They do not add new carbon to soils, but transfer it in space and or time. It is therefore important to calculate the build-up of plant biomass to estimate carbon inputs. A major challenge in this context is to quantify plant residues on the surface (litter, stubble) and below ground (roots, exudates). The amount of plant residues depends on both environmental conditions at a site and physiological properties of the respective plant. Several studies report data on plant residues, but because of the large effort required for data collection, the available data are still not sufficient for reliable site-specific calculations of plant biomass inputs.

Biochemical properties of different materials affect the turnover times of carbon in soils. It has been shown that roots contribute more to soil organic matter build-up than shoots (Kätterer et al., 2017). Further, carbon supply with microbially pre-digested substrates such as compost, is more effective in stabilizing carbon in soils than green plant biomass (Spaccini and Piccolo, 2019). With regard to the carbon balance, however, it has to be considered that original substrate carbon is lost in the composting process.

Carbon outputs

Carbon leaves the soil via microbial respiration as methane or as dissolved organic carbon (DOC). The most important pathway is microbial respiration, and this process occurs in all soils without waterlogging. Respiration depends on the microbial community, the environmental conditions and the properties of organic substrates. Suboptimal conditions (stress) and a wide C:N ratio of substrates result in decreased efficiency of the microorganisms to incorporate carbon, while carbon losses per unit input increase (Manzoni et al., 2012).

Methane is produced in soils with waterlogging when organic material is decomposed under anaerobic conditions. Methane is 38 times more effective as a greenhouse gas than carbon dioxide. The production of methane therefore is an important process with

regard to climate change, but with limited relevance in arable farming systems on non-flooded soils. Methane is also consumed by certain bacteria in soils under aerobic conditions, which counteracts greenhouse gas emissions.

Dissolved organic carbon is a side product of microbial organic matter turnover. It may be leached into water bodies and even reduce freshwater quality. Even though the leaching of DOC is not a C loss to the atmosphere, this process may require more attention in the management of organic matter.

Carbon saturation

Soil organic matter dynamics follow an exponential time course, approaching a theoretical steady state if an input of organic material with a given quality is applied continuously. The process of carbon saturation depends on soil properties that are related to the physical protection of organic matter, and on environmental conditions that regulate biological activity and turnover (Craig et al., 2021). Carbon saturation is usually calculated as the difference between actual and maximum mineral-associated organic carbon stocks, where the fine fraction of soil texture (clay, or clay + fine silt) is used as a basis. Carbon saturation limits the potential for further sequestration of carbon at a site. Soil with a low carbon saturation may sequester more additional carbon than soil that has already reached a high stage of saturation.

The approach has proven applicability, even though it has been criticized because this calculation does not capture less stable soil carbon pools that may contribute significantly to total carbon storage (Barré et al., 2017). In fact, soils with a low texture-related potential to stabilize carbon (sandy soils) may hold considerable amounts of carbon under appropriate management (Roß et al., 2022). In this situation, carbon is not stored by protection from turnover. Rather, it is 'stored' in turnover by balancing supply and decomposition at a high level. The unprotected carbon pool must be taken into account in carbon sequestration strategies, calling for a more dynamic perspective (Fig. 1). It is necessary to consider that a large supply of organic carbon is usually associated with a considerable input of nitrogen, which can cause environmental damage. On the other hand, the supply of soils with organic matter improves the growing conditions for the plants, which should facilitate N uptake and export. Increasing the unprotected carbon pool, therefore, is a very valuable strategy for the ecological intensification of crop production, but requires thorough monitoring and management of nutrient flows.

There are no reliable global estimates of carbon saturation in managed soils. However, regional calculations (e.g. Wiesmeier et al., 2014) showed that arable soils had a lower carbon saturation than grassland and forest soils. Correspondingly, arable soils had a large calculated potential to store additional carbon, while forest soils were almost saturated. It should be noted, however, that the calculations were performed according to the texture-related approach described above, where potential 'dynamic' carbon storage in less stable fractions is not accounted for.

Carbon sequestration strategies

Carbon sequestration in soils can be achieved either by reducing the turnover of organic matter or by increasing organic inputs. Reducing turnover requires techniques that decrease the accessibility of organic matter to soil microorganisms, or the application of material with reduced degradability (i.e. biochar). The advantage of this strategy is that C storage is quite permanent if conditions remain unchanged. On the other hand, the strategy neglects the importance of organic matter supply to foster biological processes and soil health.

Soil health, a term referring to the ability of soils to function as a living system with a high degree of self-regulation, is largely dependent on soil biology (Lehman et al., 2015). As organic matter plays a crucial role in the soil food web, its decomposition and turnover are of vital importance for maintaining soil health. In particular, turnover provides microorganisms with energy and nutrients, contributes to the biological regulation of pathogens as well as to the decomposition of pollutants, and releases

Fig. 1 Dynamics of the unprotected (a) and protected (b) carbon pools in the soil. Carbon changes in both pools over time, but the dynamic is much stronger in the unprotected pool. Carbon sequestration strategies need to consider both pools, calling for a dynamic perception of carbon sequestration. The dotted line (c) denotes the physical maximum of carbon protection in the specific soil.

plant-available nutrients. Moreover, soil health has the potential to reduce the need for external inputs, such as synthetic fertilizers and pesticides (Lehman et al., 2015), which in turn reduce greenhouse gas emissions in the industrial sector.

In contrast to decelerating turnover, increasing organic matter inputs is a synergistic solution for carbon sequestration and the management of soil health. Techniques in this strategy include diverse crop rotations, agroforestry, cover cropping, and organic fertilization. It must be considered, however, that this strategy builds up a very dynamic C pool whose maintenance requires continual effort. Further, increasing organic inputs may even stimulate a priming effect on organic matter turnover, or induce emissions of N₂O (nitrous oxide) and CH₄ (methane), which severely impair the positive effect in climate change mitigation.

Soil management practices for carbon sequestration

Land management has a large impact on carbon dynamics. In this context, the form of land use (cropland, grassland, forest, etc.) is more important than the management within land-use types. The conservation or establishment of land-use types with large carbon storage is therefore of crucial interest for maintaining or improving C storage in soils. With cropland soils, there are various options to improve C levels. Improved crop rotations, residue management and agroforestry mainly increase C inputs, while organic fertilization and biochar application supply carbon in more stable forms that in addition improve soil fertility and health. Further, reduced tillage can affect turnover conditions, and mineral amendments may be used to stabilize carbon better in soils. Carbon sequestration in grassland soils can be improved by adapted grazing, cutting and fertilization strategies.

Land-use change

The conversion of intensively managed cropland to more extensively managed land-use types such as grasslands or forests results in a long-term increase in SOC in most cases (Poeplau et al., 2011). In particular, the establishment of permanent grassland on former cropland is a promising strategy to sequester C, although potential GHG emissions related to grassland use have to be accounted for. A change in land use from cropland to forest normally also results in C sequestration, but the intensity of the SOC increase is strongly related to the tree species. Afforestation with coniferous species often results in a shift from stable to labile SOC that is prone to faster turnover and degradation. For the conversion of grassland to forest there is no consistent effect on SOC stocks, although in temperate regions SOC tended to decrease (Poeplau et al., 2011). The build-up of SOC induced by the conversion of cropland to grassland or forest has often been related to increased C inputs into the soil. However, in temperate regions, recent research has shown that the C input into cropland and grassland soils is similar, but that the quality of organic matter (more root-derived C inputs in grassland soils) rather than quantity controls the differences in SOC stocks between land-use types (Jacobs et al., 2020).

Cropland soil management

Improved crop rotations and crop residue management

Increasing the diversity of cropping systems has been shown to be a valuable tool for the build-up of SOC (McDaniel et al., 2014). In particular, the integration of legumes, ley grassland, cover crops, undersown crops, deep-rooting crops and perennial crops into cropping systems often leads to sequestration of C, mainly by increasing root-derived C inputs. An increased retention of crop residues is another strategy to enhance the C input into agricultural soils and their SOC stocks. In particular, the retention of aboveground harvest residues such as stubble, beet leaves and straw or their return via organic fertilizers (slurry, manure or digestate) is an efficient way to increase C inputs and thus SOC stocks (Bolinder et al., 2020). However, it should be mentioned that the use of harvest residues, e.g. for biogas production or utilization of the straw, might be more advantageous in some cases in terms of climate protection than their retention on agricultural land to increase SOC stocks.

Organic fertilizers or amendments

The return of exported harvest residues to agricultural land in the form of organic fertilizers such as manure, slurry, digestate and compost is a central component of a balanced OM supply to soils and decisive for sustainable cultivation with regard to nutrient recycling (Gross and Glaser, 2021). However, an increase of SOC based on external organic fertilizers does not represent C sequestration, as organic matter is merely relocated and locally concentrated. Such a relocation reduces the SOM reproduction potential of the areas from which the external organic matter originates. Nevertheless, organic fertilizers do contribute to C sequestration indirectly when crop yields and thus C inputs increase due to improved soil fertility.

Biochar

Amending agricultural soils with thermally converted organic matter (biochar) contributes to C sequestration due to its high stability against microbial degradation (Lehmann et al., 2006). In general, a pyrolysis temperature >450 °C is needed to produce biochar that has high overall stability in order to decrease its turnover time in soils and to contribute to C sequestration. However, the effects of the spatial redistribution of organic matter mentioned above in the context of organic fertilizers have to be taken into account. Benefits in terms of C sequestration, improved soil fertility and yields by biochar have so far mainly been demonstrated in tropical and subtropical soils and to a much smaller extent in temperate soils (Jeffery et al., 2017).

Agroforestry

Agroforestry systems integrate woody species in agricultural land and contribute to C sequestration, mainly due to increased above- and below-ground C inputs. Evidence for C sequestration in soils of agroforestry systems was mainly found in tropical and subtropical regions, but also in temperate environments (Chatterjee et al., 2018; De Stefano and Jacobson, 2018). The incorporation of trees in agricultural land may result in additional C inputs by tree roots and rhizodeposition, particularly in subsoils, but also by litterfall, the return of pruning residues, understory vegetation and increased yields on adjacent agricultural land (De Stefano and Jacobson, 2018). Moreover, reduced soil disturbance and erosion, and retarded decomposition of recalcitrant tree litter may contribute to observed SOC increases in agroforestry systems.

Reduced tillage and deep inversion tillage

It is often assumed that reduced tillage or no-till systems may contribute to C sequestration due to improved soil aggregation and thus physical protection of organic matter, while conventional tillage leads to a disruption of (macro)aggregates and increased mineralization of organic matter. However, meta studies and systematic reviews that also considered subsoil layers have provided evidence that reduced tillage and no-till systems merely induce a vertical redistribution of C and do not contribute to a net C sequestration (Luo et al., 2010). In reduced tillage/no-till systems SOC stocks are often increased in the upmost topsoil (0–10 cm), but are lower in the lower topsoil compared to conventional tillage, probably because of reduced incorporation of organic matter. In contrast, deep inversion tillage in soils with compacted subsoil layers (so-called hardpans caused by natural compaction processes, or indurated layers caused by ploughing) or for pasture renewal may contribute to C sequestration as the burial of C-rich topsoil material results in reduced decomposition of OM, while fresh OC inputs in exposed subsoils depleted in C may be effectively stabilized (Alcántara et al., 2016).

Mineral amendments

The application of mineral amendments such as clay-rich materials to agricultural soils is a promising strategy to increase their SOC storage potential. In addition to the incorporation of external clay-rich substrate in topsoils, subsoil material is often mixed into sandy topsoils to improve their chemical and physical properties, reduce soil erosion and nutrient leaching and increase SOC stocks (Schapel et al., 2018). Moreover, the incorporation of crushed silicate rocks such as basalt is discussed as an option to sequester inorganic C in the form of stable carbonates. Silicate by-products from industrial processes such as steel slag could also be used. However, evidence for organic or inorganic C sequestration by mineral amendments is still poor and additional GHG emissions related to mining or excavation, grinding, transport and the application of minerals have to be taken into account (Chenu et al., 2019).

Grassland soil management

Several improved grassland management practices are discussed that increase SOC stocks in managed grassland soils. In grazed grassland ecosystems, improved grazing management such as optimized grazing intensity or holistically planned grazing may contribute to C sequestration (McSherry and Ritchie, 2013). In general, reduced grazing intensity or spatial and temporal grazing exclusion normally results in increased SOC stocks because of increased above- and below-ground C inputs, particularly in semi-arid environments. In temperate regions, optimized grassland management intensity with regard to the frequency of cutting and fertilization may increase SOC stocks (Conant et al., 2017). Managing plant diversity in temperate grasslands could also be a strategy to foster C sequestration due to increased rhizosphere C input (Yang et al., 2019). Moreover, sward renewal and integration of deep rooting and/or leguminous species could result in increased belowground C inputs and increased SOC storage.

Carbon sequestration for the mitigation of climate change

There is increasing interest in carbon sequestration in soils as a strategy for the offset of GHG emissions to mitigate climate change. Until now, carbon sequestration in soils has not been included in the United Nations Clean Development Mechanism (<https://cdm.unfccc.int/>), or in the European Emission Trading Mechanism (Directive (EU) 2018/410). However, more private sector initiatives for voluntary climate impact compensation have discovered carbon sequestration in soils as a promising business model to counteract climate change and generate income for farmers by selling carbon credits to companies and other clients (Wiesmeier et al., 2020). In principal, this development has to be appreciated, as it raises awareness about the great importance of soils and soil services. Further, measures for carbon sequestration in managed land can have multiple benefits in addition to carbon storage. At the same time, constraints and limitations of carbon sequestration have to be taken into account to make use of the potential benefit and avoid trade-offs.

Constraints of carbon sequestration for climate change mitigation

Concerning potential carbon sequestration in soils, approaches such as the “4 per 1000” initiative have been criticized because of their exaggerated estimates and lack of consideration of the feasibility of the measures. The “4 per 1000” initiative accounts for the

physical limits of carbon accumulation in soils, but an increase in carbon stocks of 0.4% per annum is hardly achievable and realistic as a global average. Rumpel et al. (2020) summarized the barriers and constraints of the initiative. The authors not only identify biophysical, but also socio-economic and political issues that need to be addressed. With regard to biophysical barriers the authors recall that the potential increase of carbon contents in soils depends on the stage of carbon saturation, and on environmental conditions. At the interface of environmental and management factors, the availability of organic matter to build up SOM must be taken into account. Further, cultural traditions and or socio-economic conditions and political issues can make it difficult for farmers to adopt new techniques and revise their farming systems. In a regional case study from Germany, Wiesmeier et al. (2020) calculated a potential mean annual carbon stock increase of 0.1‰ as a realistic scenario. This is in accord with Schlesinger and Amundson (2018), who assume that carbon sequestration in soils may decrease net carbon emissions to the atmosphere by roughly 5%. It must be noted, though, that this number does not comprise indirect beneficial effects of organic matter build-up.

Carbon supply in a systems perspective

Carbon sequestration must be contemplated in a systems perspective. In fact, increasing soil carbon has many more advantages apart from storing a certain amount of C that benefit climate change mitigation: As stated in the introduction to this chapter, carbon supply is usually related to the build-up of soil fertility, which in turn allows for a reduction of external inputs, such as synthetic fertilizers and pesticides. Currently, the indirect climate change mitigation potential of carbon sequestration has not been quantified on a global scale because the effects usually result from complex system changes, and not from carbon build-up alone. However, there is considerable evidence for ecological services provided by the organic matter supply to soils. According to Bommarco et al. (2013), increasing SOM amounts and diversifying crop rotations are the most effective measures to promote the support of ecological services in agroecosystems. Based on a large European survey, Garrat et al. (2018) showed that increased SOC in soil can partially replace nitrogen fertilizer and reduce pest pressure in cereals under conventional management, even without further agroecological optimization of farming systems. Luo et al. (2018) found that organic amendments significantly improved crop yields and soil functions in a global meta-analysis of field experiments. Against this background, Baveye et al. (2020) argue that the improvement of soil functions by organic matter supply is of much greater relevance for climate change mitigation than carbon sequestration itself.

It is definitely necessary to look at management options for carbon sequestration in a different way. Wiesmeier et al. (2020) pointed out that measures for carbon sequestration may have so-called leakage effects on other sites, meaning that improving carbon sequestration by increasing carbon inputs may withdraw carbon from other sites. This is particularly relevant for all measures that reduce productivity (such as set-aside), as they may induce land-use changes or other forms of intensification at another site to compensate for the decrease in product output. Further, it has been suggested that organic matter supply may lead to reduced N efficiency use and increased losses because of problems in synchronizing N release and uptake in agricultural soils. In addition, nitrogen release from organic amendments might even increase GHG emissions, and N₂O in particular. Undoubtedly, there is also a need for improvement and optimization in the development and implementation of agroecological management strategies and techniques. The potential benefit of organic matter supply to soils for improved ecological and economic performance of agricultural systems is much greater than the potential disadvantage.

Carbon sequestration in soils compared with fossil C emissions

The most important threat to climate change mitigation by carbon sequestration in soils, however, is that this option may distract from the need to phase out C emissions from fossil sources. In the scientific literature, it is well-recognized that carbon sequestration directly and indirectly contributes to climate change mitigation, but that there is definitely no alternative to the phasing out of fossil C emissions in the near future (Seddon et al., 2020). As described in this chapter, carbon is dynamic in soils, and the potential of soils to store carbon further is not infinite. Therefore, the attempt to offset fossil C emissions by carbon sequestration in soils is a risky strategy without a long-term perspective. Permanent storage of C, which would be the prerequisite for the true offset of fossil C emissions, cannot be guaranteed. The balancing of fossil C emissions by carbon sequestration in soils may even have a detrimental impact on climate change, especially if carbon is lost again from soils over time (Thamo and Panell, 2016). Furthermore, the finite potential of carbon accumulation in soils makes carbon sequestration in soils a transitional solution on the way to a post-(fossil) carbon economy.

Conclusion

Building up soil carbon contents through agricultural management is much more than merely removing carbon from the atmosphere. On the one hand, agricultural soils worldwide have a great potential to sequester atmospheric carbon and compensate for a, yet limited, amount of GHG emissions. On the other hand, organic matter in soils is a key factor of soil fertility and health, and therefore plays a crucial role in the ecological intensification of agricultural production. Building up soil organic matter is thus both a mitigation and adaptation strategy in the context of climate change.

There is no permanent storage of organic matter in soils. Soil carbon is stored reversibly in fractions with different stability and turnover times due to protection from microbial breakdown and chemical recalcitrance. Long-term stabilization of organic carbon

in managed soils depends on the sorptive capacity of the mineral fraction and on compactness of the soil structure. In agricultural soils, the largest proportion of the carbon is incorporated in organic matter that is involved in biological turnover. Unlike other carbon capture and storage technologies, carbon sequestration in agricultural soils must be understood as a dynamic process, where carbon is not stored in a permanent pool, but in the cycling of organic matter.

Organic matter supply to soils is both a key driver of carbon build-up and of soil fertility, therefore, farming *with* carbon should replace the idea of farming *for* carbon. Carbon sequestration in managed soils is both a prerequisite and an effect of ecological intensification in agricultural production. It therefore has a great potential to counteract climate change, but it does not discharge other sectors from their responsibility to phase out fossil carbon emissions in the near future.

Abstract

Tillage is the mechanical manipulation of the soil to modify or ameliorate its physical condition with regard to plant growth for human and animal food production. Tillage operations include incorporation of fertilizers or crop amendments, seedbed preparation, seeding, and post-emergent cultivation for weed control. The requirements for tillage depend on the crop, the soil type and the climate conditions. Inadequacy of the tillage intensity with these conditions locally might lead to severe damages of the environment and the crop production systems.

Key points

- Tillage is the mechanical manipulation of the soil needed for crop production.
- Tillage operations are combined into various tillage systems.
- Requirement for tillage must be carefully investigated to ensure a sustainable crop production.

Introduction

Tillage is an activity of preparing the land for growing crops by mechanical agitation of soil. Soil movement can also occur due to natural (e.g., freeze-thaw processes) and biotic (e.g., earthworm movement) processes; however, tillage generally refers to the direct intervention of a soil manager, who uses tillage tools to modify, manipulate, or ameliorate the soil physical condition. This activity can be human-powered, draft animal powered or carried out using powered machinery. In a crop-production system, tillage is employed to facilitate crop establishment, modify soil structure, incorporate fertilizers and soil amendments (e.g., lime and manure), control plant residues and weeds, and alleviate both climatic and soil constraints to agricultural production. Over time, various tillage tools have been developed to perform specific soil-moving operations. A combination of tillage operations and their timing results in the development of a tillage system to provide specific functions in given situations. Tillage is a fundamental part of cropland farming. It has an instant and strong effect on soil physical properties and soil biology, and soil physical properties affect the outcome of soil tillage (Fig. 1).

Tillage systems

Traditionally, most tillage operations consist of primary tillage followed by secondary tillage (Fig. 2). This traditional combination is referred to as conventional tillage, although this term is also applied to any tillage system that has been adopted for a period. Primary tillage usually consists of relatively deep (15–25 cm) tillage, using a moldboard or chisel plow. In contrast, secondary tillage is relatively shallow (5–10 cm) and used to pulverize and consolidate the soil to form a suitable seedbed. Both primary and secondary tillage are usually conducted uniformly across a field. The last few decades of the 20th century have seen concerted efforts to reduce the level of energy used for plant production, and therefore the amount and degree of tillage by adoption of reduced, minimum, or shallow tillage. Reduced tillage allows a reduction in depth, degree, and frequency of tillage, while minimum tillage refers to the minimum soil manipulation necessary for crop production or other soil tillage requirement. Shallow tillage involves restricting tillage to a shallow soil depth (less than 15 cm). In no-tillage systems, crop seeds are planted directly into the stubble and

Fig. 1 Tillage has a strong and instant effect on soil physical properties. This diagram represents the dynamics of the air-filled and water-filled volumes (both available and unavailable water for plants) in a cultivated topsoil during a year: (a) autumn plowed topsoil before the start of cultivation in spring, (b) after the seedbed preparation and the seeding in spring, (c) the lowest height of soil surface above the plowing depth after the harvest, and (d) immediately after the autumn plowing. Fig. 2 Tillage systems with various tillage intensity. Ploughing and diskking are primary tillage operations, while cultivating and planting are secondary tillage operations. After Hallett PD and Bengough AG (2013) Managing the soil physical environment for plants. In Gregory PJ and Nortcliff S (eds.), *Soil Conditions and Plant Growth*, 1st edn, pp. 238–268. Blackwell Publishing Ltd.

residue of the previous year's crop (Figs. 2 and 3). A special planter is generally required to penetrate residual vegetation and a compacted soil surface. However, occasional tillage may be required to control weeds that are resistant to herbicides.

Overall, the main impetus behind the reduction in tillage intensity is to reduce the degree of soil degradation often associated with excess tillage, and to reduce tillage costs in commercial agriculture. In many cases, uniform tillage across a field may not be required or desirable. For row crops (e.g., maize (*Zea mays* L.), sugar beet (*Beta vulgaris* L.), oilseed rape (*Brassica napus* L.)) tillage can be restricted to specific areas across a field (strip or zone tillage). Seedbed preparation can be confined to the planting row, while the remaining area receives less or a different type of tillage treatment. In these not planted areas, a coarse soil structure is maintained to facilitate water infiltration. Further to this, crop residues can be kept on the soil surface outside the planting rows to reduce evaporation and protect soil surface from rain drops and wind.

Basic soil tillage operations consist of soil inversion or fragmentation (Table 1). Specific tillage tools operating at a range of soil depths are used to achieve these operations. Soil inversion is best accomplished using a moldboard plow, while soil-loosening can

Fig. 3 Examples of tillage operations in a long-term tillage and rotation experiment: (a) moldboard plowing to 20–25 cm depth; (b) rotavator harrowing to 8–10 cm depth; (c) harrowing to 3–4 cm depth; (d) no tillage using a single disk planter. Photos: Lars Andreassen.

Table 1 The characteristics, aims and some essential effects of common tillage operations.

Tillage operation	Main machines involved	Principal aims and effects achieved on soil structure
Inversion tillage	Moldboard plow, offset disks	Inverts, fragments and loosens the soil; buries weeds and residues from the previous crop, incorporates manure and organic amendments.
Ridge till	Ridge tillage cultivator and modified planter	Soil is pushed by pairs of winged tines to form ridges up to 20 cm deep. The harvest residues on the surface are removed and the top of the ridge flattened by a horizontal blade so that the seed is planted in the ridges without residue cover in the row. Contrasting soil conditions are created in the ridge and between the ridges. Residues and organic amendments are mixed with soil in the sides of the ridges each year. The ridges warm up quicker than flat land in spring, in part because the ridges drain more readily.
Reduced tillage	Rigid or sprung tines, disks, powered tines, rotary implements	Fragments and loosens the soil. Harvest residues can be left on the soil surface. Can be performed to a depth greater than 100–150 mm (deep reduced tillage) or to a depth of less than 100 mm (shallow reduced tillage).
Stubble-mulch tillage	Tines or disks	Fragments and loosens the soil. Residues are retained on the soil surface.
Zero-tillage/no-till/direct drilling	Drill with tines or disks	Seed is drilled into the stubble of the previous crop with minor soil disturbance confined to the row and does not extend below seeding depth.
Zone or Strip-tillage	Rigid or sprung tines	Tillage with coulters or rigid tines (down to 15 cm below the soil surface) in a narrow strip of soil. Seeding takes place in the tilled zones, with the inter-row area remaining undisturbed and where crop residues are retained.
Strategic tillage	Rigid or sprung tines, disks, powered tines, moldboard plow	A system predominantly using reduced tillage equipment but includes the use of moldboard plowing as a flexible responsive to seedbed concerns (typically weeds) or the need to incorporate organic amendments, manure or crop residues.
Rotational plowing	Rigid or sprung tines, disks, powered tines, moldboard plow	Reduced tillage or no-till is used routinely for soil preparation but a plow is used at key points in the rotation.
Secondary tillage	Powered or unpowered tines, disks, rotary implements, rollers	Tillage practices used after the principal tool to create a seedbed and provide additional weed control
Remedial tillage	Subsoiler tines, rotary spades or mole plow	Deep tillage techniques used to remediate soil compaction.

be achieved using several tillage tools. Rotary cultivators are well suited for mixing soil and often used to mix soil fertilizer and organic amendments into the soil. Plant residues can interfere with some tillage tools. Coulters or disks are often used to cut or divert crop residue away from the immediate tillage zone. Repeated or heavy traffic in the field might lead to soil compaction in the subsoil, i.e., the soil below the tillage depth. Subsoiling is the attempt to mechanically loosen the compacted subsoil (remedial tillage operations, Table 1). An efficient subsoiling operation should be performed at a water content where the soil is friable to avoid smearing. A mechanically loosened subsoil has a low strength and can be easily and severely recompacted.

In many cropping situations and climates, innovations in tillage practices have led to the development of conservation tillage or conservation agriculture systems. Conservation tillage is a generic term used to describe tillage systems that have the potential to protect soil by reducing soil loss (by wind and water erosion) relative to some form of conventional tillage (Fig. 2 and Table 1). A well-accepted operational definition of conservation tillage is a cover of 30% or greater field area of crop residue on the soil surface after planting. Thus, leaving crop residues on the soil surface is fundamental for conservation tillage systems. Conservation agriculture can be viewed as an extension of the conservation tillage concept as it includes: (1) minimal soil disturbance, (2) Permanent soil organic cover (residues and living plants) and (3) Species diversification.

Why tillage?

The traditional aims of tillage are to improve soil structure for crop growth, incorporate organic amendments into the soil, and to control weeds. The last goal can often be met by use of herbicides, and this has led to the development of no-tillage systems, where tillage is confined to soil disturbance associated with crop seeding or planting (Figs. 2 and 3). Soil tillage is also involved in soil-water conservation and regulation, and in soil-erosion control. Table 2 outlines some of the various pros and cons of tillage in agricultural systems. The role of tillage in soil structure improvement has various facets related to crop growth and productivity. Tillage is conducted to improve soil functions such as water and air regulation and flow, increasing infiltration, improving drainage, and enhancing the water-storage capacity of the soil. It is used to create a desirable aggregation size distribution conducive for crop seed-soil contact. Soil loosening to alleviate soil compaction can also be a key objective of tillage. Such an operation is labeled subsoil loosening or subsoiling when it is carried out below the normal depth of tillage (20–30 cm). For subsoiling, straight, curved or parabolic shanks are typically used. Tillage is also used to manipulate crop residues, either by burying and mixing them into the soil, or by retaining them at the soil surface to serve as mulch for soil protection or as a barrier to reduce runoff and soil erosion, improve water infiltration and limit evaporation. The depth and intensity of tillage needed are not the same for all soil types and cropping situations. Some soils, due to climate (e.g., cool, wet soils) or type (e.g., high clay or sand content, or poor permeability), have a relatively high need for tillage. In contrast, there are soils with a relatively low tillage requirement, as they are able to regenerate soil structure under natural processes associated with soil wetting and drying, and freeze-thaw processes.

Why NOT tillage?

Improved and optimal growth condition for the crops has been the aim of tillage for thousands of years (Fig. 4). However, the need for soil tillage should be carefully investigated, as operations performed in non-optimal conditions might be detrimental for plant growth and the environment (Table 2). For almost 200 years ago, the moldboard plow opened new possibilities in plant production allowing for crop rotations that include grass, and for incorporation of manure, both of which resulted in higher yields. However, the extensive use of moldboard plowing to convert natural arid grassland, the Great Plains, to arable land in North America resulted in severe dust storms in the 1930s, damaging significantly both the ecology and the agriculture. These events, referred as the Dust Bowl in the United States, sparked interest in conservation tillage (Faulkner, 1943). Plowing is both energy and time consuming. The lack of horses to pull the plow during the 1st World War encouraged farmers to drop the plowing operations (Holladay, 1918). A similar trend was observed in connection to the energy crisis in the 1970s, and during the last decade owing to the high prices of fossil fuels. Nowadays, the need for plowing is again questioned in order to reduce CO₂ emissions to the atmosphere.

Table 2 Pros and cons of soil tillage.

<i>Pros</i>	<i>Cons</i>
Ideal seedbed	Breakdown soil structure
Weed control	Promote runoff
Reduce compaction	Promote erosion
Incorporate organic matter	Destroy macropores
Disease control	Promote drying
Soil warming	Disturb soil biota
Break up crust	Increase temporally SOM turnover
Improve infiltration, drainage, water storage	Increase daily temperature variation in soil
Decrease pesticide use	Increase energy consumption and working time

Mixing, loosening and inverting the topsoil layer affect the soil quality over time (Karlen et al., 1994). High erodibility after plowing has also been a strong driver in the development of plowless systems. The 1930s Dust Bowl in the United States initiated and accelerated the development of conservation tillage technology in North America. Erosion affects soil quantity and quality, and has negative effects on the environment (eutrophication of surface water bodies, reduced water quality, sediments with large amount of adsorbed phosphorus or pesticides). When tillage operations are performed in wet conditions, the soil may be compacted, and the soil functions may be impacted. Soil tillage operations, especially moldboard plowing, increase evaporation and water loss from the soil. The inversion of the top layer by plowing produces a soil surface without any plant residues that usually protect it from sealing and crusting, from erosion and evaporation. In dry areas, conservation tillage (see the “Tillage system” section for a definition) helps reducing evaporation and keeping the soil water for plant growth (Duley and Matthew, 1947). Plant residues on the soil surface help also to reduce the daily soil temperature variation, mainly by increasing the reflection of the solar energy (i.e. by increasing the albedo of the soil surface) (Hay et al., 1978). The content of organic matter is very important for quality and health of mineral soils. In soils used for annual arable cropping, the content of soil organic matter (SOM) is often decreasing over time, due to export of harvested products and residues. Soil tillage, and especially moldboard plowing, affects the SOM content mainly by mixing into the tilled layer, but not by reduction of the total amount in the soil profile (Gómez-Muñoz et al., 2021). After some years of conservation tillage, the content of SOM in the surface layer will increase, due to concentration of organic matter inputs in this layer. However, the content of SOM will decrease deeper in the soil profile due to lack of tillage induced soil mixing. Nevertheless, an increase of SOM content in the surface layer may be very important for the soil properties connected to plant growth.

Soil fragmentation in tillage

Soil fragmentation is the process of crumbling of soil fragments under applied stress. The easier it is to fragment the soil the easier it is to perform tillage (Utomo and Dexter, 1981). The ease of soil fragmentation depends on the internal soil pore structure, the soil water content or more precisely the soil water potential, the soil mechanical and hydraulic properties, and the mechanical action of the tillage implement. A soil fragment is a conglomeration of organic and inorganic particles that cohere to each other more than to the neighboring particles. The aim of tillage is to obtain an overall loosening of soil without disturbance of the microstructure of the soil matrix. In addition, the satisfactorily soil loosening should be achieved efficiently with regard to energy consumption. Therefore, brittle failure of soil fragments is desirable. Brittle fracture is the soil failure by crack propagation along the weakest planes of soil fragments. Cracks propagate rapidly through the soil fragments without a need to increase the mechanical stress applied. There is little plastic deformation associated with brittle failure, which means a low energy absorption during fragmentation. The ability of soil to display brittle failure is often quantified by measuring the tensile strength, i.e., the mechanical stress or force per unit area that is required to break it along the weakest failure planes, for differently sized soil fragments. Ideally, the soil should easily fail into a particular size range of smaller fragments—making up an ideal seedbed. This ability is labeled soil friability. A friable soil is characterized by a high ease of fragmentation of large aggregates or clods and a low ease of fragmentation of minor aggregates into undesirable small elements.

Table 3 Soil water range for tillage reported in the literature.

Soil workability limits			Soils studied	Climate	Source
Wet limit	Optimum water content	Dry limit			
$\omega = 0.24 \text{ kg kg}^{-1}$	—	$\omega = 0.18 \text{ kg kg}^{-1}$			Sitkei (1967) cited in Dexter and Birkas (2004)
—	θ at maximum Proctor density	—	Silty clay loam and silt loam	Humid continental climate	Wagner et al. (1992)
θ at plastic limit (θ_{PL})	$0.9 \theta_{PL}$	θ at which the strength of soil is twice the strength at $0.9 \theta_{PL}$	Clay loam to silty clay loam	Temperate	Dexter and Bird (2001)
θ at $\varphi = -100 \text{ hPa}$	—	θ at $\varphi = -1250 \text{ hPa}$	Loam	Tropical	Hoogmoed et al. (2003)
θ at $\varphi = -125 \text{ hPa}$	—	θ at $\varphi = -3162 \text{ hPa}$	Clay	Tropical	Hoogmoed et al. (2003)
—	0.7θ at $\varphi = -50 \text{ hPa}$	—	Sand to clay	Continental temperate humid to continental dry	Mueller et al. (2003)
$\omega = 0.40 \text{ kg kg}^{-1}$	—	$\omega = 0.33 \text{ kg kg}^{-1}$	Clay	Temperate	Gülser et al. (2009)

θ : volumetric water content; ω : gravimetric water content; φ : matric potential.

Water range for tillage

The soil normally displays optimal friability at a specific range in water content—the so-called water range for tillage. At wetter state, the soil will tend to deform plastically and at a drier state the soil will need strong force to fragment and tend to pulverize rather than fragment it into a desirable size range of smaller fragments. The water range for tillage will typically increase with increasing soil organic carbon content and decrease with degree of compaction and clay content (Table 3).

Outlook

Soil tillage has been essential to improve and sustain crop growths since the very beginning of agriculture 12,000 years ago. Various tillage operations have been developed since, human or animal powered, then leading to the modern mechanized tillage systems. The type of tillage operations and the intensity of tillage should be carefully investigated for given pedo-climatic regions to ensure a sustainable crop production without detrimental consequences on the environment. The timing, with regard to soil mechanical conditions, and the intensity of a tillage operation will determine the quality of the results. Appropriate tillage systems will prevent soil erosion, soil compaction, flooding, and pollution of water bodies.

Abstract

Weed management interacts with soil in many ways. Its primary aim of reducing the number and biomass of non-crop plants means that it simplifies agroecosystems, although it produces negative ecological and environmental outcomes including reducing soil health. At the same time weed management is utterly essential, as without it weeds would overrun crops within a few years, dramatically reducing yield. Integrated weed management (IWM) is where, physical (e.g. mechanical hoeing), chemical (i.e., herbicides), biological (e.g. biological control) and ecological (e.g. rotations) techniques are used in an integrated and symbiotic manner. Integrated Weed Management is the approach recommended by the international weed science community.

Glossary

Allelopathic Suppression of plant growth and seed germination by a toxin released from a nearby plant.

Broad spectrum herbicide Herbicide that kills a wide range of plants, both monocotyledons (grasses) and dicotyledons (broad leaves).

Dedifferentiate The process by which differentiated plant meristems (buds) i.e., root, stem and cambium, can change into another form of meristem (e.g., root meristem changes into shoot meristem).

Fallow To leave an agricultural field bare of plants, either using herbicides, or more typically tillage.

Herbicide resistance Herbicide resistance is the inherited ability of a plant to survive and reproduce following exposure to a dose of herbicide normally lethal to the wild type. In a plant, resistance may occur naturally or be induced by techniques such as genetic engineering or selection of variants produced by tissue culture or mutagenesis.

Herbicide tolerance Herbicide tolerance is the inherent ability of a species to survive and reproduce after herbicide treatment. This implies that there was no selection or genetic manipulation to make the plant tolerant; it is naturally tolerant.

Organ of perennation The structure within a plant that allows it to persist over multiple years, e.g., a bulb or tap root.

Raunkiaer system A plant categorizing system based on life-form, devised by Danish botanist Christen C. Raunkiaer.

Residual herbicide A herbicide that is applied to the soil and kills weed seedlings as they germinate and emerge.

Selective herbicide A herbicide that will kill some plant species (the weeds) but not others (the crop).

Systemic herbicide A herbicide that translocates (moves) within a plant's vascular system.

Therophyte Annual plants that complete their lifecycle rapidly in favorable conditions and survive unfavorable seasons as seeds.

Translocate To move within a plant's vascular system (phloem and xylem).

Weed seed rain The deposition of viable weed seeds from their parent plant into the weed seedbank.

Weed seedbank All the weed seeds that reside in the soil.

Key points

- Weed management aims to reduce plant biodiversity to benefit the crop, but reduced biodiversity has multiple negative environmental outcomes including on soil health.
- Weed management is essential, without it weeds will overrun crops, and yield will be drastically reduced.
- Integrated weed management (IWM) integrates many different weed management techniques achieving synergies among them, is the approach recommended by weed scientists.
- Techniques such as mechanical weeding and herbicides tend to have the greatest negative impacts, particularly when non-crop plant numbers are reduced to very low levels and soil is left bare.
- Techniques that use biological and ecological approaches, e.g. living mulch, have lower negative impacts and can also have positive impacts.
- Weed management is therefore a balancing act between achieving sufficient weed management to achieve good yields, while, minimizing the negative impacts it can have on soil and all aspects of the farm ecosystem.

Introduction

Weed management interacts with soils in multiple ways. The primary aim of weed management is to limit weed populations below the levels where they cause economic losses, both in current and future crops. Weed management therefore deliberately aims to reduce plant biodiversity, both in the amount and range of non-crop species, which produces a cascade of negative ecological effects, including reduced soil health. Where weed management achieves a very large reduction in weed populations bare soil can result which is at risk of erosion and other damage. Tillage (e.g. mouldboard ploughing/inversion tillage) is an integral part of weed management in many farming systems, particularly cropping systems (e.g., cereals and vegetables), and tillage's negative impacts on soil are well documented, including in this encyclopedia. In response to the harmful effects of tillage, especially inversion tillage, on soil health, reduced/minimum tillage and no-tillage systems were developed and have been widely adopted. Changing tillage systems can have large impacts on both weed flora as well as soil health.

The soil is where the weed seedbank is situated, and particularly for therophyte weeds, managing the weed seedbank is critical for effective weed management, especially under non-chemical and integrated weed management systems (Fig. 1). Soil health and

Fig. 1 Weed seed banks can contain millions of seeds giving rise to large numbers of weeds, *Digitaria sanguinalis* (L.) Scop. uncontrolled in maize (*Zea mays* L.).

function also have a large impact on the weed seedbank, as there are many organisms in soil, from microorganisms through invertebrates to vertebrates that predate on seeds, so soil management and soil health can affect how much of the weed seedbank is lost to predation. In comparison, mechanical techniques to reduce the weed seedbank, such as fallowing are highly damaging to soil due to both repeated tillage and absence of living plants, resulting in compaction, loss of structure, reduction in soil biological diversity, etc.

Integrated weed management (IWM) is the approach promoted by weed scientists as the most effective long-term and damage limiting approach to weed management. It systematically integrates physical, chemical, biological and ecological approaches using the technique that achieves optimal weed control with the fewest negative outcomes for the wider environment for any given issue. However, physical and chemical techniques are often harmful to soil, and greater use of biological and ecological techniques is required. Additionally, over reliance on chemical control can lead to herbicide resistant weeds. One such technique is cover cropping, which has many permutations and can achieve good weed management while at the same time avoiding the damage and consequences of physical and chemical techniques and even improving soil health at the same time.

System level farm tools for weed management, for example, diversified rotations, can have positive effects on soil health, e.g. the inclusion of a pasture phase in a cropping rotation, improves all aspects of soil quality and health, and reduce the soil seedbank and therefore the need to use harmful agrichemicals.

While weed management has multiple effects on soil, many negative, effective weed management is critical in farming, particularly cropping. If not controlled, weed populations can rapidly reach exceptionally high levels to the point that crop yield is dramatically reduced, even to the level of complete crop loss. Further, for any given crop or pasture there will always be many different species of weeds present and any given weed species can infest a very wide range of crops and pastures, which means weeds are the ubiquitous pests of crops and pasture. This contrasts with invertebrate pests and diseases (e.g. fungi and bacteria) of plants which are typically highly host specific, i.e., any given pest can attack only a narrow range of host species, and vice versa any given crop species is only attacked by a small range of pests and diseases. Weeds can also host crop plant pests and diseases. Effective weed management is therefore vital for successful agriculture and horticulture.

Weed management therefore interacts with soil in many different ways, and while often having negative effects, there are many techniques available to help ameliorate negative effects and increase positive effects. Weed management is therefore a balancing act, between achieving sufficient weed control for good crop yield and quality, while minimizing negative impacts on soil and the rest of the farm environment.

Weeds

What is a weed?

While those working with weeds in the field have a clear intuitive understanding of what a weed is, there is no agreement on a precise definition. For example, the Weed Science Society of America defines a weed as “A weed is a plant that causes economic losses or ecological damage, created health problems for humans or animals, or is undesirable where it is growing,” while the European Weed Research Society defines weeds as “any plant or vegetation, interfering with the objective or requirements of people.” However, both of these highlight that defining a plant as a weed is a subjective not objective decision, particularly when it comes to defining a specific plant or population of plants at a given time, as weeds. For example, a crop species such as *Triticum aestivum* L. (common wheat) can become a weed in the following year in a crop of *Brassica napus* L. (oil seed rape).

The advent of the herbicides around the 1940s, provided farmers with new tools that made the control of weeds much easier. Many plants that had not previously been considered weeds, because the effort to control them was much greater than the benefits of removing them, were reclassified as weeds. This has tended to result in all non-crop plants now being considered weeds. However, other approaches exist; for example, traditional farmers in the tropical agroecosystems of south-eastern Mexico divide plants in the field into three groups, 1 the crop, 2 buen monte (good plants) and 3 mal monte (bad plants) (Chacón and Gliessman, 1982). Buen monte are plants that establish themselves in the field (i.e., they are not planted) but are recognized as still being of value, often as food, but also for other benefits, e.g. medicinal. Therefore, these plants are not removed, and may even be cultivated if they are of sufficient value and or scarcity. These plants can be defined as non-crop plants. Mal monte are plants that establish themselves in the field, but have no value or worse, have negative values (they are bad). For example, they can smother the crop and reduce yield, or are toxic/harmful, so they are therefore removed, i.e., they are weeds. Therefore, for these farmers not all non-crop plants are weeds, rather, at the individual plant and species level, a decision is made as to whether they are good albeit non-crop plants or bad and therefore weeds (Fig. 2).

Within the developed world with intensive farming systems a similar reappraisal is occurring. For example, Storkey and Neve (2018) argue that weeds have value in agroecosystems not only for environmental values such as biodiversity, but also within an ecological framework if they are managed. The increased weed diversity can be beneficial for yield, system stability, sustainability and resilience, e.g. in the face of weather extremes due to climate change. As weed management can have a number of negative impacts on soil, and other environmental outcomes, e.g. insect populations and biodiversity, moving from the view that any non-crop plant is a weed and must be controlled to a more nuanced view that non-crop plants can have multiple benefits, including agronomic, is going to be vital to reduce the negative outcomes of weed management, particularly the evolution of herbicide resistant weeds.

Fig. 2 Mal monte (bad plants), in this example the mal monte was the previous crop of radish (*Raphanus sativus* L.) but now a mal monte in the present crop of barley (*Hordeum vulgare* L.).

Why manage weeds?

The primary reason for managing weeds is that they compete with crop and pasture plants, for nutrients, water and or light, thereby reducing yield/production and therefore decreasing the amount of food and fiber produced, and where crops are sold, profit. Weeds can also be harmful in other ways: for example, they can harbor crop pests and diseases, they can reduce the quality of produce (e.g. *Avena fatua* L. (wild oat) seed contaminating wheat grain for flour, weed seeds contaminating planting seed, or burs in sheep's wool), they can be toxic to livestock, and increase production costs from in-field weed plant control, to post harvest contamination and cleaning.

Weeds are also a ubiquitous pest, in that in any given crop or pasture, many tens, if not hundreds, of weed species will be present, over a very large range of populations, and, any given weed species is able to infest a very wide range of crops or pasture (cropping weeds and pasture weeds tend mostly to be different species; cropping weeds mostly annuals, pasture weeds mostly perennials). Weeds therefore have a 'many-to-many' relationship, meaning that all crops and all pastures will have weeds present (there is no such thing as a weed-free crop or pasture), and any one weed species can occur in many different crops or pasture. In comparison, invertebrate pests and diseases typically have a 'one-to-one' or 'few-to-few' relationship with their hosts, in that any given species of pest or disease can only attack one or just a few host species, and any one host is susceptible to a tiny fraction of the total invertebrate pests and diseases that attack plants. If environmental and ecological conditions are favorable, any crop species may be unaffected by most of its potential pests and diseases at a given time and in ideal conditions it may be completely free from all of them. Weeds are therefore a far greater threat to crops and pasture than invertebrate pests and diseases.

Many weeds, particularly annuals and biennials, can produce prodigious amounts of seed, for example tens even hundreds of thousands of seeds per plant. If uncontrolled, the populations of these weeds will grow exponentially, such that within a few years, their sheer numbers will make it impossible to grow crops. Successful weed management is therefore not just focused on controlling weed plants growing within a crop or pasture, it is even more focused on preventing weeds going to seed and increasing the size of the weed problem in the future.

The many harmful attributes of weeds, their ubiquitous nature and their massive reproduction rates mean that effective weed management is always required in every crop and pasture if the long-term productivity of farming is to be maintained. Effective weed management is therefore essential.

Plants and soil health

All plants: crops, non-crop plants and weeds perform the key function of the primary suppliers of energy and nutrients to soil biology which in turn controls soil health (Bender et al., 2016). This is at the heart of the interaction of weed management and soil. Since their development in the mid 20th century, herbicides have taken over weed control in most developed countries, which is now leading to the problems of herbicide resistant weeds and to depleted soil biology.

Plant diversity

Living plants are the primary controlling factor of soil biology and therefore soil health. This is because, as autotrophs/primary producers, it is plants that harvest energy from the sun and use that to extract carbon dioxide from the atmosphere to create complex

organic compounds (i.e., carbohydrates, fats, and proteins), which are then transferred to the soil ecosystem directly by living plant roots and also to a lesser extent from dead plant material, both roots and foliage (Sokol et al., 2019). Where plants are eliminated from a soil, by herbicide application or tillage for example, the soil's primary source of energy and complex organic chemistry is lost, and its health starts to decline.

Further, ecological science has now clearly demonstrated that plant diversity is also critical for maximizing soil health attributes, such as soil organic matter/soil carbon, and ecosystem diversity, particularly microbial diversity. A diversity of plant species delivers a much greater diversity of complex organic compounds, and due to different root morphologies they explore different soil depths and aggregate spaces which in turn affects nutrient and water dynamics all of which creates even greater soil biodiversity (Weisser et al., 2017). Plant biomass is critical to soil health but is optimized with greater plant diversity.

Bare soil

A lack of plants is highly detrimental to soil health. In tropical and temperate climatic zones of most ecosystems, soil is generally covered by plants, both living and their dead residues, e.g. the detritus layer in forests. This plant cover protects the soil from harmful factors such as becoming hot under direct sunlight, damage to soil structure from rain-drop impact, flooding from high rainfall events that can erode soil, high winds that can blow soil away and compaction from livestock. Intensive weed management often results in bare soil among the crop plant stems, which is therefore at risk of being eroded by wind and water (sheet, rill and gully erosion) and an overall reduction in soil health.

Where plants are removed from soil for extended periods, e.g. herbicide strips under perennial crops such as apples and grapes, soil health can be dramatically reduced, resulting in severe compaction, loss of structure, organic matter and soil biology.

A balancing act

The fundamental aim of weed management is to reduce the number and populations of weed plants in crops and pastures, and therefore weed management inherently works against soil health. It is therefore critical to understand the details of the interaction of weed management and soil health, and how best to minimize harm and maximize positive outcomes, i.e., a balance is required. Weed control needs to be good enough so that, in both the short and long terms, weeds do not have negative impacts on crops and pasture. However, weeds must be controlled only to the point that yield loss and other negative production outcomes of weeds are avoided, but no further, or replace *mal monte* with *buen monte*, such as cover crops (discussed below), so that the negative environmental outcomes of weed management are minimized. That balancing act is the focus of the rest of this chapter.

Weed and soil management interactions

The Weed Seedbank

In arable and vegetable systems most crop species are short-term annual plants, therefore the weed species that have a good evolutionarily fit in these systems are also short-term annuals that can complete their lifecycle within the production time of the crop. Longer lived plants, i.e., biennials and perennials, do not survive as living plants but are typically killed between crops by tillage or herbicides. Under the Raunkiaer system, these short-term annuals are classified as therophytes, as the resting buds are in the form of seeds. From this perspective it is not the weed plants growing in the crop that are the fundamental part of annual weeds' lifecycle, rather it is the seeds in the soil, i.e., the weed seedbank, that is the permanent life stage of annual weeds. Effective annual weed management therefore needs to have a strong focus on the weed seedbank in the soil; so once again, weed management and soil are intimately interlinked.

The size of the weed seedbank can vary by orders of magnitude, for example, Rahman et al., (1996) found the number of weed seeds per kilogram of soil collected from six maize (*Zea mays* L.) fields in Waikato, New Zealand, varied from 1 to 695 seeds kg⁻¹ dry soil. The number of weeds germinating from that soil was strongly correlated ($r = 0.96$) to the number of seeds in the seedbank (Rahman et al., 1996). While there is little or no direct interaction between the weed seedbank and crop plants, they tend to emerge simultaneously (competition) and a large weed seedbank will result in a large number of in-crop weeds which will have a large negative impact on the crop. Therefore, minimizing the weed seedbank is critical for reducing in-crop weed plants.

The primary means of managing, i.e., reducing, the weed seedbank is to prevent in-crop weed plants seeding and refilling the weed seedbank, a process called the 'weed seed rain.' Managing in-crop weed plants is the dominant focus of herbicide-based weed management, which is so effective in crop weed management and will also minimize weed seed rain. Here, practices such as cover crops that reduce, but do not eliminate, seed rain are better than herbicides for managing the weed seedbank. There can also be a large loss of seeds in the weeks immediately following seed shed through predation by vertebrates such as birds and rodents, soil dwelling invertebrates such as carabid beetles, and over the longer term by microorganisms such as fungi (Gómez et al., 2013; Kennedy, 1999). Both soil and weed management can have a significant impact on seed predating species and their abundance, both positive (e.g. cover crops), and negative (e.g. herbicides), so in turn it can have a considerable impact on the weed seedbank in both the short and longer term.

For non-herbicide weed management systems, management of the weed seedbank is particularly important. One technique for diminishing the weed seedbank is tilled fallow, where the soil is repeatedly tilled to shallow (<10 cm) depths, during the growing

season, to encourage weed seeds to germinate and then kill the emerged weed seedlings (Rahman et al., 2001). While this can be highly effective, regular tillage and keeping fields free from vegetation over extended periods, it is highly damaging to soil structure, reduces organic matter and overall soil health, so this technique has fallen out of favor. A more targeted approach involves false and stale seedbeds. These are implemented by setting up the land for planting, either with tillage or herbicides, but, then delaying planting by one to 3 weeks to allow weed seeds to germinate, particularly where tillage has stimulated germination. Then in a false seedbed the weedlings are killed through very shallow re-tillage (<5 cm), or in a stale seedbed by herbicides or thermal weeding, e.g., a flame weeder (Merfield, 2015). These can be very effective at reducing in-crop weeds, while having much less impact on soil health than fallow, because of the short duration when the soil is free from plants and the low intensity of the re-tillage used.

The weed seedbank occupies the soil which means that its management and soil management are intertwined. What is good for seedbank management may be damaging to soil and vice versa, whereas actions that benefit soil, e.g. leaving more weed plants, may increase the size of the weed seedbank. Again, balance is required.

Tillage

The purpose of tillage is often considered to be to improve soil structure, enhance water infiltration and aeration, incorporate fertilizers, increase crop seed germination and boost crop and pasture growth, however, a key function of tillage is also weed management. There are two main approaches: first, to eliminate living weed plants and also plant residues from the field prior to establishing a new crop or pasture. Second, tillage changes the vertical distribution of the weed seedbank and different forms of tillage or no-tillage produce different distributions that can have important implications for weed management.

Vertical distribution of the weed seedbank

In reduced tillage systems the seedbank is stratified closer to the soil surface while inversion tillage creates a more even distribution through the soil profile (Fig. 3).

Weed species differ in their response to different tillage intensities with some increasing under reduced tillage and others decreasing, with often opposite outcomes for inversion tillage (Table 1).

Tillage approaches can therefore be varied to address particular weed problems. For example, where grass weeds build up in no- and min-tillage systems, occasional use of inversion tillage, e.g., once in 5 years, will bury the grass seeds at depth. Grass seeds lack the hard seed coat of dicotyledons, therefore they die after a few years of burial and are eliminated from the seedbank.

Vegetation clearance, minimum and no-tillage

Traditionally, clearing vegetation was done with the mouldboard plough which inverts the soil, burying the weeds and residues on the soil surface and bringing up soil free from plants and residues. The scientific evidence is very clear that tillage has multiple negative impacts on soil, with inversion tillage having the biggest effect. A classic example of this was the dust bowls in North America in the 1930s and 1940s. They resulted in the introduction of reduced and minimum tillage approaches such as disk harrows that only till 5 to 10-cm deep, which are used instead of the plough to kill off weeds and incorporate residues. The logical end point of reducing tillage intensity is no-tillage systems, where only the absolute minimum amount of soil and residue is disturbed to drill and germinate crop seeds successfully. No-tillage systems are particularly important in regions with low rainfall

Fig. 3 Distribution of weed seeds (total no 200 g⁻¹ dry soil) in the soil profile after cultivation treatments (Rahman et al., 2000).

Table 1 Influence of tillage systems on densities of selected summer annual weed species in *Zea mays* L. (maize) and *Glycine max* (L.) Merr. (soybean) production systems.

and erosion prone soils, such as in central South and North America. No-tillage systems, however, rely on broad-spectrum, systemic herbicides, principally glyphosate, to replace the role of tillage in eliminating weeds and other plants prior to sowing new crops, such that the use of herbicides for this purpose is referred to as chemical ploughing (Baker and Saxton, 2007). However, the frequent and continuous use of the same type of herbicide is a risk because of selecting herbicide resistant weeds. The main aim of minimum and no-tillage is protection of the soil. To quote Baker and Saxton (2007; p. 1.) “No farming technique yet devised by humankind has been anywhere near as effective as no-tillage at halting soil erosion and making food production truly sustainable.”

In addition to achieving the minimum level of soil disturbance necessary to accomplish successful crop emergence, no-tillage also aims to maintain as high a level of soil cover as possible, either by living plants or plant residues. This is also a key aim of conservation agriculture. Soil cover is vital to protect the soil from wind and water erosion and from becoming excessively hot due to solar radiation; therefore, it helps to maximize soil health by regulating soil temperature and water dynamics. No-tillage therefore reduces farming’s impact on the soil by minimizing soil disturbance and maintaining soil cover, but it is only currently possible by using herbicides.

This shows the close relationship between tillage, including no-tillage, and weed/vegetation management, and how different tillage/no-tillage approaches affect soil health.

Soil applied herbicides

Herbicides are divided into two groups, foliar and soil applied, based on how they are absorbed by plants. To be effective, soil applied herbicides face multiple challenges in that factors such as soil texture (especially clay content), organic matter content, biological activity, pH, temperature and moisture content can all affect the herbicide’s effectiveness. Most of these interactions are well understood and for any given herbicide there are detailed guidelines for successful use (Zimdahl, 2018a).

Soil applied herbicides can also directly negatively affect soil biology including microorganisms, though it is generally accepted that the effects are temporary rather than permanent (Zimdahl, 2018b). Leaching of herbicides, into ground and surface water is also a risk. Leaching is regulated by the same soil properties that determine the herbicide’s effectiveness, e.g. clay and organic matter particles that adsorb a herbicide and reduce its efficacy will also reduce its leaching. A herbicide’s properties, e.g. solubility, also have a large impact with rainfall and irrigation being additional factors (Zimdahl, 2018b).

In-crop weed management

Integrated weed management

In-crop weed management has been dominated by herbicides since the 1950s, however, the international weed science community is clear that herbicide centric weed management systems face multiple challenges, such as evolved resistance to herbicides, and that changing to an integrated weed management (IWM) approach is essential for ongoing effective weed management (MacLaren et al., 2020). Like all integrated pest management systems, IWM monitors weed problems in crops and pasture, and only when action or economic thresholds have been reached, is a weed control activity undertaken. Those weed control activities can be broken down into four main approaches: physical, such as mechanical hoeing; chemical, i.e., herbicides; biological, e.g. biological control agents (BCAs); and ecological, e.g. rotations, and intercropping. When all four approaches are combined in a symbiotic and integrated fashion IWM is achieved (Fig. 4).

However, unlike insect and disease integrated management, where past, current and future pest occurrences are only weakly linked or not linked at all, weeds are strongly linked over time because of the weed seedbank for annual and biennial weeds, and because perennial weeds live for many years. Therefore, IWM needs to manage this temporal nature of weeds actively by instigating

Fig. 4 Combining physical, chemical, biological and ecological weed management techniques to create integrated weed management (IWM).

proactive measures, for example, diversified and long rotational sequences, rather than relying on monitoring and then controlling living weed plants in crops and pasture. A further problem of threshold-based weed management is that some weeds are difficult to control once they have emerged and thus require the prophylactic use of soil-acting residual herbicides.

Herbicides and mechanical weeding

While the weed science community is clear on the need to move to IWM, change on the farm is being achieved more slowly. Mainstream farmers often still rely heavily on herbicides, and alternative farming systems, such as organic agriculture, which prohibit the use of synthetic herbicides, often relies heavily on mechanical approaches such as interrow hoeing. The latter prohibits the use of synthetic pesticides and herbicides and often relies heavily on mechanical approaches such as interrow hoeing. Both of these can achieve good weed control, such that the vast majority of the plant species and biomass in the field is the crop alone. As discussed at the start of this chapter, monoculture and bare ground are both deleterious for soil health and many other environmental outcomes, so, alternatives are required. This is particularly pertinent to herbicide resistance, as a move by mainstream farmers from herbicides to mechanical techniques is not necessarily beneficial for the soil or wider environment, resulting in reduced soil structure and organic matter, increased compaction, and greater use of fossil fuels. Therefore, biological and ecological approaches should be favored. Cover crops are one such example that also have the potential to improve soil health at the same time.

Cover crops

Cover crop is the general term to describe plants that are grown for purposes other than for immediate sale to generate profit. The terms cash crop and non-cash crop are also used to describe the two purposes. The reasons for growing cover crops are many; the key ones include building soil organic matter, improving soil health, fixing nitrogen, and reducing leaching, soil erosion, agrichemical runoff, and weed management.

Cover crops/non-cash crops are sub-divided into a diverse range of approaches. The key message regarding all the cover crop approaches is that they use biology/ecology rather than physical and chemical means to manage weeds. By increasing the number of plant species and biomass in crops and pasture, positive gains can be made for soil health; the opposite of what physics and chemistry typically achieve.

It should be noted that there are no agreed definitions of the various cover crop approaches. There is variation in use among the English speaking countries and even within them, with some terms being used interchangeably and the same term being used to describe different approaches.

Cover crops can be initially divided into two main approaches: first, those grown in the period between cash crops and second, those grown with the cash crops. In the first approach, there is no issue of competition between the cash and cover crops, though there will be lag effects due to changes in plant nutrients, moisture and residues. For the second approach there is the potential for significant competition between cash and cover crops which has to be carefully managed, but it is also possible to have cover crops that have a synergistic effect on the crop and therefore increase yield.

Green manures and catch crops for nutrient management

The term green manure is mostly used for cover crops that can fix atmospheric nitrogen into reactive nitrogen that can be used by living organisms. These are mostly legumes, which have a symbiotic relationship with diazotrophs that live in nodules on the roots. These are of particular value in organic agriculture which prohibits the use of synthetic and soluble nitrogen fertilizers, so green manures are an important route by which nitrogen is replaced.

A catch crop aims to catch or take up nutrients that could potentially leach out of a soil, principally nitrogen, and convert inorganic nutrients into organic forms which are more resistant to leaching and also provide nutrition for the soil biome, augment soil organic matter, improve soil structure, etc.

Green manures and catch crops are both grown in-between cash crops. In tropical regions this might be at the same time, whereas typically in temperate regions they are grown over winter when no cash crops are growing. Their benefit for weed management is that they can compete strongly with weeds, preventing them from proliferating and seeding. They can also provide habitats for seed predators such as beetles and rodents. Some of the plants are allelopathic, so can further inhibit weed plant growth and also the germination of weed seeds, and in addition their residues/ground cover can prevent the emergence of weeds.

Smother crops

Smother crops are similar to green manures and catch crops in that they are grown in-between cash crops, but, their main purpose is to smother weeds through strong competition from both roots and foliage. These are mainly used to manage particularly challenging weeds such as *Cirsium arvense* (L.) Scop. (Californian/Canadian thistle) and *Elymus repens* (L.) Gould (couch grass). These types of weeds are hard to kill as they have creeping roots or stems that can spread rapidly through the soil. They often have substantial organs of perennation which provide them with stores of energy and nutrients to regrow after damage, and most can also dedifferentiate and regrow even after having been damaged or broken up by tillage. Control of these weeds can be very challenging, even with herbicides, and where they fail the alternative is often extended fallow, sometimes with deep cultivation that is highly damaging to soil health.

The smother crop species need to be matched to specific weeds to ensure that they can compete effectively with the weed. For example, *C. arvense* has a creeping root system at a depth between 20 cm and 1 m, and when broken up by mechanical tillage all the pieces can dedifferentiate to produce new roots and shoots resulting in more plants than before. Few systemic herbicides can translocate sufficiently throughout the root system to kill it entirely. One smother crop option is an autumn sown mixture of *Secale cereale* L. (ryecorn/cereal rye) and *Vicia* species e.g., *Vicia sativa* L. (common vetch). This achieves sufficient biomass and height over winter when *C. arvense* is dormant, such that when the thistle emerges in spring it immediately experiences considerable competition for light, which increases further as the ryecorn can grow to a height of two meters. This is twice the typical height of *C. arvense*, with the vetch climbing up the ryecorn thereby blocking nearly all light to the thistle. In addition, ryecorn has a highly competitive, deep, fibrous root system which competes strongly with the thistle roots. *Elymus repens* has shallow creeping stems which can dedifferentiate at the nodes into both shoots and roots, such that it easily regrows after being broken up. *Trifolium pratense* L. (red clover) is an effective smother crop because it grows higher than *E. repens* and has thick dense foliage that blocks the light to the *E. repens* leaves. Red clover is a legume that can fix its own nitrogen giving it a competitive advantage if the soil is deficient in nitrogen over couch grass, which will be nitrogen deficient. Smother crops are therefore a particularly clear illustration between physical and chemical approaches that can harm the soil, compared with biological/ecological approaches which can have positive benefits for soil health.

Living mulch

Living mulches, also known as companion cropping, are where a non-crop plant is grown under the crop plants to cover the soil completely. A classic example is *Trifolium repens* L. (white clover) growing under *Zea mays* L. (maize). The clover's green leaves intercept and change the light spectrum reaching the soil which has a strong inhibitory effect on weed seed germination, and if weed seeds do germinate, they face strong competition from the white clover. In addition to being a highly effective means of controlling weeds, living mulches can have many other benefits such as supplying nitrogen to the crop, providing shelter, nectar, alternative prey and pollen (SNAP) to beneficial insects that can help control crop pests (Gurr et al., 2017). This is in addition to the benefits to soil compared to the bare ground created by herbicides and mechanical weeding. However, in dryer climates living mulches can compete for water with the crop, so the technique is not universal.

Relay cropping and undersowing

Relay cropping and undersowing are where the following crop (cash and non-cash) is sown into an established crop. Relay cropping, as in relay race, is where the following crop is established close to harvest of the preceding crop, often being drilled between current crop rows. Undersowing is where the following crop (cash and non-cash) is established soon after the preceding crop is sown and is often broadcast, for example, a pasture or a green manure. In terms of weed management, there is no tillage between the changes in crops so the germination impetus from tillage is lacking, nor is there a period where the soil is plant free; these both inhibit weed seed germination and establishment. For soil health there is a greater diversity of plant species during the overlap period, no tillage, and a continuous cover of plant foliage and living plant roots, i.e., there is no plant free gap between crops, all of which is beneficial for soil health.

All of these cover crop examples illustrate the potential of using biological and ecological techniques to manage weeds between and within cash crops, achieving excellent weed control while avoiding the damage that can be done to soil health by physical and chemical techniques.

System level techniques

As discussed in the IWM section, due to the temporal nature of weeds, system level techniques are also vital for effective weed control. Rotations are the prime example of a system level technique, together with plant mixtures/intercropping, and grazing management techniques in pastoral systems.

Rotations

Rotations are where different crop species, both annual crops and pasture, are grown in sequence over time. For example, two to three years of pasture, then *Triticum aestivum* L. (wheat), *Solanum tuberosum* L. (potatoes), *Allium cepa* L. (onions), *Avena sativa* L. (oats), for 1 year each and then returning to pasture. Rotations have multiple benefits for both production and the farm ecosystem, including weed management (Liebman and Dyck, 1993) and soil health (Merfield, 2019). By increasing the diversity of crops grown, no weed species has continual ideal conditions for growth and reproduction, particularly when there are both permanent crops such as pasture and short-term annuals, such as potatoes and onions. Most annual weeds cannot survive in pasture as they are preferentially eaten by stock and likewise the perennial weeds that prosper in pasture are killed by tillage and the crop renewal process involving the use of herbicides. Also varying planting between spring and autumn crops, e.g. winter and spring wheat and spring planted oats, changes the time of crop establishment and therefore which weed species emerge with the crop. For soil health, rotations increase the diversity of plant species through time, and in the pasture phase it is possible to have a highly diverse range of species. Pasture, being perennial, and with the fibrous roots of grasses, achieves far greater gains in soil health across all measures than any cropping system, even no-tillage, so its inclusion in a cropping rotation is exceptionally beneficial.

Crop and pasture mixtures - intercropping

As discussed at the start of this chapter, increasing the diversity of plants in space, i.e., growing a mixture of crop or pasture species together (intercropping) is beneficial for soil health. It can also improve crop production factors such as weed, insect pest and disease suppression, an overall increase in yield compared to the same area of land sown in a monoculture system i.e., the land equivalency ratio (LER) (Nyfeler et al., 2009; Wendling et al., 2017), as well as providing wider environmental and ecosystem benefits (Tamburini et al., 2020). The improved weed management in mixed species is principally due to the different species taking up different ecological spaces or niches leaving less ecological space for weeds.

As the number of plant species in a mixture increases, however, particularly if they are not closely related, e.g. a mixture of monocotyledons and dicotyledons, then the number of herbicides that can be used that will not kill one or more of the crop species decreases considerably. Selective herbicides are easiest to use in monocultures, which is partly why organic farmers, who are prohibited from using any synthetic herbicides, are more likely to use crop mixtures. However, the increased level of weed control that can be achieved with mixtures, potentially with a small amount of mechanical weeding around crop establishment, may give sufficient weed control so that herbicides are not required.

Grazing management

The traditional approach to grazing is 'set stocking' where livestock are spread out across all the available pasture. This results in stock preferentially eating the most palatable plants and leaving unpalatable, toxic and other harmful plants, which by definition in a pastoral farming system are weeds. The continuous grazing of palatable plants and non-grazing of weeds results in the weeds having a competitive advantage ecologically and they proliferate. Rotational grazing, 'rotates' /moves stock around the available pasture, with only small areas being made available to them at any one time. Once they have grazed the defined pasture area, they are moved to the next area, and prevented from returning to the area they have just grazed. This allows the pasture to recover from grazing and achieve a considerable percentage of its maximum biomass. This means the pasture is more competitive with the weeds because it is not being continually grazed and the weeds ungrazed. Also, many pasture weeds are simply unpalatable rather than being harmful, and in a rotational grazing system these are often inadvertently eaten by the stock together with the palatable plants; therefore, they also suffer a setback then with grazing. The intensity of rotational grazing varies considerably, with stock being left on a larger area of pasture for a period of up to a week, through to very small areas of pasture with the stock being moved several times a day. Well implemented rotational grazing is therefore a key weed management tool for pasture. Pasture can grow considerably more biomass and achieve greater rooting depth under rotational grazing and the stock are not continually trampling the soil as in set stocking system, therefore, long-term rotational grazing management can also improve soil health by increasing soil organic matter and structure and reducing compaction.

Conclusion

Weed management can have significant impacts on soil: both positive and negative. Many of the negative outcomes are associated with physical and chemical management techniques, while positive outcomes are often the result of biological and ecological techniques. Like much of farming, weed management and weed science are in a state of considerable change, even a paradigm shift. Just as chemical herbicides largely replaced mechanical weed control in the 1950s, with increasing herbicide resistance, a lack of new herbicide chemistry since the 1980s and withdrawal of older chemistry due to new regulatory requirements, many farmers are returning to mechanical techniques. The latter are often updated with sophisticated technology to the point that individual weeds, even at the cotyledon stage, can be identified by computer vision systems and each weed then eliminated individually, e.g. by high voltage electricity. However, replacing chemicals with mechanical weeding is not necessarily positive for soil health, and may be more harmful. What is required is an increased focus on and use of biological and ecological techniques such as cover cropping, intercropping, diversified rotations and rotational grazing, which can achieve excellent weed management while also being beneficial for soil.

Abstract

Agricultural landscapes, particularly in hilly to mountainous tropical terrains, have been constructed through millennia by local, peasant or indigenous societies on the basis of their traditional environmental knowledge. Agricultural terracing is an excellent example of an agricultural landscape. As ancient as agriculture itself, terracing has been practiced by rural communities in fragile or marginal environments in all continents, from North Atlantic subarctic islands to dry and wet tropical regions. The ancient techniques of terrace building, still used in many regions by small-holders, peasants managing subsistence agriculture, have been complemented or replaced by contemporary techniques employing mechanical equipment particularly for excavation in the frame of modern agriculture. In this chapter, emphasis will be on the first type of terracing, i.e., as a traditional agricultural landscape. Terraces have been largely devoted to subsistence agriculture, and were able to feed substantial numbers of people under various political and organizational systems. Regardless of the environmental characteristics and the level of social peasant organization, the purposes of any type of terrace are soil and water conservation and rain-fed or irrigated agriculture in marginal or fragile sloping terrains. In every instance, local, traditional slope management plays a key role. Abandonment has been also occurring in various places through history, probably accounting for the decline of terracing in many sites. Despite differences in the type of human-environment relationship, abandonment seems to follow economic crises in agriculture that in turn trigger migration.

... where flat lands suitable for agriculture do not naturally exist
man has been forced to create such surfaces artificially.

Spencer and Hale, 1961, p. 1.

Key points

- Agricultural terraces are discussed as cultural landscapes and heritage sites.
- Traditional environmental and slope knowledge is highlighted as a basis for terrace development.
- Focus is on terracing in tropical mountainous developing countries.
- Case studies are put forward to depict a balance between current farming in terraces and terrace abandonment.

Introduction

Agricultural landscapes, particularly in hilly to mountainous tropical terrains, have been constructed through millennia by local, peasant or indigenous societies on the basis of their traditional environmental knowledge. Agricultural landscapes are cultural landscapes involving either temporary or permanent interventions on slopes or valleys aimed at managing and improving local environmental conditions to develop usually complex agricultural systems. Sometimes referred to as rural landscapes, they have been highly regarded as efficient means to use and conserve natural resources particularly plants, soils and water. It has even been argued that cultural landscapes may provide more efficient access to resources than natural landscapes.

In many instances terraces have become part of the cultural heritage of human societies at the national or regional level. The United Nations Educational, Scientific and Cultural Organization (UNESCO) institutionalized the concept of world heritage, and in 1972 established the convention of the world's cultural and natural heritage. In this frame more than 1000 sites have been recognized since as natural, cultural or mixed heritage sites around the world. One site category is that of cultural landscapes, among which agricultural sites are prominent. Likewise, the UNESCO geopark network includes significant agricultural landscapes. In addition, since 2005 the FAO has designated 62 Globally Important Agricultural Heritage Systems (GIAHS) in 22 countries, most of them tropical, developing ones (see UNESCO and FAO websites).

Agricultural terracing is an excellent example of an agricultural landscape. As ancient as agriculture itself, terracing has been practiced by rural communities for millennia in fragile or marginal environments on all continents, from North Atlantic subarctic islands to dry and wet tropical regions (Fig. 1).

Terracing is considered a paramount human modification of sloping land for social adjustment to changing environmental conditions and to develop sustainable agriculture (Varotto et al., 2019). The practice has deserved scientific attention since the 1950s for both archeologic and environmental academic fields (for example, Spencer and Hale, 1961). The interest expanded during the last decades. In 2010, the International Terraced Landscapes Alliance (ITLA) was founded to revisit terraces as a cultural resource to meet current social demands: agriculture, food, tourism, among others (see ITLA web site, below).

While it is not clear whether there was one single center where terracing originated, several reports indicate that in China terracing is as old as 4500 years, in the Peruvian Andes 4400, in central Mexico 3500 and in Yemen, Jordan and Israel at least 3000 years old. Terracing traditions coupled to soil management seem to have been initiated separately from, but later on became integrated with, traditions of hydraulic management in some regions. The ancient techniques of terrace building, still used in many regions by small-holders and peasants managing soils and water for subsistence agriculture, have been complemented or replaced by contemporary techniques employing mechanical equipment particularly for excavation in the frame of modern agriculture. In this chapter, emphasis will be on the first type of terracing, i.e., as a traditional agricultural landscape.

Basic definitions and typology

An agricultural terrace is a portion of humanly created flat terrain, disposed step-like downslope or across a water channel. In this way both the gradient and the length of the slope or the channel are reduced. Overland flow, interrill and rill erosion of the soil are thus controlled, while soil sedimentation, infiltration capacity and residual humidity are stimulated. The purpose of terracing is to create a relatively flat surface for cultivation in otherwise poorly suitable strongly sloping terrain with shallow soils. Locally, terraces are referred to by different names in different languages. For instance, *bancas* and *andenes* are widespread terms for terraces in Spanish speaking countries.

A terrace comprises two components. On the one hand a stone, soil or shrub (or a combination of those) riser perpendicular to the main slope gradient or to the water flow direction in a channel. The base of the riser upslope is at the same level as the upper portion of the riser downslope. On the other hand, a second element is the flat surface immediately above the riser (Fig. 2). In this design, traditional builders expect that following storms sediment will be delivered downslope and the terrace will be filled up with fresh upslope surface materials. With time, the riser height must be increased to trap sediments efficiently downslope. In addition, a terrace may be accompanied by a canal to distribute incoming runoff and to allow for irrigation. The length and width of a terrace

Fig. 1 Modern terracing in contrasting environments. (A and B) Grassy terraced land nearby Tórshavn, Faroe Islands; (C) Sloping terraces in Fuerteventura, Canary Islands. Photographs by the author.

Fig. 2 Cross-channel terrace with stone riser, under rain-fed cajete maize (*Zea mays* spp.) at the onset of the rainy season. Mixteca Alta geopark. (A) at the onset of the rainy season. (B) at the end of the rainy season. Photographs by Quetzalcóatl Ramírez-Orozco.

will depend on the slope or channel gradient. Slope conditions will in turn control the process of digging and filling whenever feasible.

Terraces have been classified in several typologies according to form, dimensions, building materials and landscape position (among others, see [Spencer and Hale, 1961](#)). One simple, albeit comprehensive classification, encompasses three major types: cross-channel terrace to control ephemeral drainage and trap sediment delivered along water courses; contour or sloping terrace, ranging from a barely modified slope to a stone-built, excavated bench terrace, usually irrigated; valley-floor terrace on relatively flat terrain sometimes used for irrigation purposes.

Terrace types are based on designs that may be as elementary as simple cross-channel weirs, trapping incoming soil and water downslope. They may evolve through transitional forms up to more complex structures involving backslope digging and earth filling of the foreslope against the embankment if regolith is deep enough. In areas of shallow surface material filling may have been accomplished by hand, in baskets, or even removing top soil to allow the washing downslope of the subsoil material. Irrigation may also require complex canal design either to manage excess water in wet tropical areas, or to conserve limited water supply in dry regions. More complex designs require stronger social organization and engineering capabilities.

Regardless of the environmental characteristics and the level of social peasant organization, the purposes of any type of terrace are soil and water conservation and rain-fed or irrigated agriculture in marginal or fragile sloping terrains. In every instance, local, traditional slope management plays a key role.

Traditional slope management and geographic distribution of agricultural terracing

Traditional slope management is strongly based on traditional soils and landscape knowledge by farmers worldwide, but with a focus on hilly to mountainous tropical countries. This type of knowledge involves knowledge on landform, runoff, soil and farming practice; it is derived from long-term observations, coupled to religious beliefs and transmitted orally from generation to generation.

Slope management by farmers focuses on slope dynamics as governed by gravity; in fact it deals with the management of runoff and sedimentation. It is well documented that this involves the recognition of overland flow, soil detachment, transport and sedimentation by water, as well as soil quality for cropping along the *catena*, from summit to base level through slope, foot-slope and toe-slope positions. Terrace farms practice traditional cropping systems, either rain-fed or efficiently irrigated, involving limited use of external inputs and minimizing environmental impacts.

Recognition of the need to build terraces on sloping terrain and the benefits that could be obtained seem to underpin the decision-making process leading peasants to invest time, energy and resources to intervene on slopes and channels. Traditional knowledge is crucial in such processes, involving human-environment relationships at a local level but in disparate sites. Various local practices, which produced similar outcomes elsewhere, share common features and may be based on general principles behind local slope management.

This may explain why terracing has originated and developed in different parts of the world without any contact between social groups involved in the practice. The number of cases and the size of areas cropped either currently or in the past amount to very large figures. An inventory would be a titanic effort outside the scope of this chapter. Here, a short list of countries where terracing is or has been important is summarized by (sub)continent. Rice terracing (paddy fields) has been reported in scientific publications for mountains in Yemen, China, Japan, Nepal, Bhutan, India, Indonesia and the Philippines. In Africa, examples in Ethiopia, Tanzania and Rwanda have been documented. For Europe, cases are reported especially but not only for the Mediterranean region (particularly Spain and Italy). In Latin America, most examples are reported in the Andes (especially Ecuador, Peru and Bolivia) and Central America (especially Mexico and Guatemala). Other cases have been mentioned for Southwest United States.

Case studies

To depict the scope of terraced landscapes, a few case studies are briefly summarized below for Asia and Latin America. In both regions, terracing has been and still is a prominent agricultural landscape feature. The cases reviewed here emphasize prehistoric origin and the challenges to continuous use by local communities.

Terracing in Asia

Honghe Hani Rice Terraces (China)

The Honghe Hani Rice Terraces in the Ailao Mountains in Yunnan Province, Southwest China are a 1300 year old UNESCO World Heritage Cultural Landscape site and an FAO Globally Important Agricultural Heritage System. The Hani people have built and maintained an impressive paddy system encompassing 3000 terraces occupying 4700 ha, over 16,600 ha of total land, and transformed the valley of the Hong River in a living cultural landscape providing food and services to the rural population in three towns and 18 villages (Bai et al., 2013).

Traditional landscape knowledge coupled to strong religious beliefs and a solid social organization allowed the Hani to develop an integrated soil and water management system on very steep slopes, from the forests at the top of the valley side at nearly 2800 masl down to the river banks at approximately 250 masl (Li, 2017). The forests upslope operate as a sponge for the roughly 1350 mm yearly average seasonal rainfall. A complex canal system distributes the water through the rice terraces downslope to reach the river channel. Downslope water movement also involves organic fertilization (manure) for terrace cultivation of several varieties of rice and other staple crops (Yuan et al., 2014).

The Hani rice system is well known for the harmonious spatial integration of its four landscape components: forest, village, terrace and river. The system has been successful in achieving a long-term combination of agroecological and livestock food production, accounting for nearly 50% of the peasant income, together with soil and water conservation, and disaster mitigation, particularly drought and hazards from mass movement (Yuan et al., 2014).

Ritual landscape components, deities and beliefs, and other immaterial features are at the core of annual religious festivals celebrating water, terrace and forest. Beliefs and local expert knowledge contribute to traditional water management. The village water manager, elected by the villagers on the basis of expertise and social recognition, controls the allocation of water to the terraces. The distribution of water is carefully calculated by means of a traditional allocation system as a function of the size of the irrigation area.

The prominent landscape aesthetic value of forest, terraces and traditional dwellings has triggered increasing tourist activity. To be sustainable, for locals and visitors, development of careful land use planning of the terrace system is desirable and that follows appropriate guidelines to face various current challenges. Beliefs and traditions as well as local knowledge in land and water management tend to diminish, especially among younger generations following access to modern education and rural to urban migration. The red rice (*Oryza punctata*, Kotschy ex Steud.) system, the major crop, is sufficient to feed local villagers, but modern cropping techniques increasingly modify the traditional system. Coordination among national cultural heritage authorities, local leaders and villagers could help to provide a proper answer to challenges (Zhan and Zhang, 2015). Research on human-environment links from both traditional and modern perspectives could also serve this purpose.

Rice Terraces of the Philippine Cordilleras (Philippines)

This steep terraced cultural landscape is on Luzon Island, in the remote Philippine Cordillera mountains, covering a range of soil and climatic conditions able to support high population densities. Of great aesthetic beauty, the wet rice contour terrace system has been built and maintained by the Ifugao ethnic group, a minority indigenous community that has occupied the region for ca. 2000 years.¹ The Ifugao terrace system also is a UNESCO World Heritage Cultural Landscape site and an FAO Globally Important Agricultural Heritage System. It is considered an example of a large-scale irrigated system outside a centralized polity (Acabado et al., 2019).

As well as the Hani rice example, major attributes of the Philippine system are the spatial distribution of landscape components where traditional cropping knowledge, beliefs and rituals are combined: the upland forest, the paddy terraces, the traditional villages and the water management system allow for irrigation through a complex network of canals (Camacho et al., 2016). Although colonial and Christian domination affected the balance in the human-environment interaction, partly guided by the local nature-inspired deities, the Ifugao managed to maintain the integrity of the system.

The Ifugao system is considered an example of adaptation of local communities to the conditions of remote environments, however, it is vulnerable to social, economic and technological changes, and it was included temporarily in the list of UNESCO endangered sites. Out migration following economic constraints, limits the availability of human power to maintain the terrace system and comply with the yearly farming calendar. A Community-Based Land Use and Zoning Plan (CBLUZP) has been recognized as critical to ensure that the conditions of integrity are maintained.

¹There exists some controversy in the literature with respect to the age of the terracing.

Terracing in Latin America. The Andes and Central Mexico

Peruvian Andes

Terracing in the Andes is emblematic. Ancient and current terrace agriculture has taken place and is still ongoing on many thousands of terraces occupying extensive areas in several countries originally occupied by the Inca (Borsdorf and Stadel, 2015). Origins of Andean terracing can be dated to pre-Inca times, but major development occurred during the climax of the Inca empire. Many rich cultural corridors have been recognized as heritage sites where sloping and bench terracing, locally called *andenes*, coupled to complex canal irrigation systems are widespread.

The Sacred Valley of the Incas, considered the heart of the empire, is one such example. Located at a short distance from Cusco, the ancient capital of the Incas, the Valley embraces many archeological sites, including the famous Machu Picchu. The Valley was a core area for maize and other staple crops because of the development of extensive agricultural terracing and irrigation systems on steep slopes along altitudinal gradients. This allowed for a large production of diverse crops to satisfy the needs of such a highly cultured civilization. Similar terracing systems occur in many other Andean valleys, connected through a large road system and also recognized as a multinational heritage site by UNESCO (Borsdorf and Stadel, 2015).

The Valley of the Colca River

A large proportion of Peruvian terraced landscape on deep Andean valleys has been abandoned following environmental and social economic change through the centuries. A thoroughly studied example is that of the Colca River Valley in the Department of Arequipa, Southwestern Andes. This semi-arid valley encompassing a relief amplitude of 3000 m has been terraced for at least 4000 years (Denevan, 2001). Original terracing was developed by the Collagua pre-Inca aboriginal group, but the peak of agricultural activity followed Inca occupation of the valley during the 15th century, a century before the Spanish conquest. Seasonal rainfall and canal irrigation allows current terrace agriculture of maize, quinoa, broad beans, alfalfa, and barley. In addition, farmers graze cattle, sheep, llamas, and alpacas on the high plateau above the valley and on fallow sloping fields.

Historic terrace abandonment has been explained on demographic grounds, particularly the decline in indigenous population during the 16th century following Spanish domination. Lack of human power to maintain terraces and canals is at the core of the process. Coupled to climate change that has affected the amount and seasonality of rainfall as well as changes in economic and political agricultural policies, abandonment has proceeded through to the present time due to out migration. The major concern however relates to conditions for restoration of an originally wise agricultural system based on terraces in an otherwise fragile and marginal environment.

Terraces in the Mexican Mixteca Alta UNESCO Geopark

The UNESCO Global Geoparks are sites and landscapes of international geological significance combining conservation with sustainable development while involving local communities. There are 169 UNESCO Global Geoparks in 44 countries. Mixteca Alta, Oaxaca UNESCO Global Geopark is in Central-Southern Mexico, a subhumid mountain region with a long cultural tradition, and home of the Mixtec indigenous group. Many of the 35 geosites of this geopark are related to the intensive use of land for rain-fed farming purposes through terracing over millennia, a system that could feed a population as large as 50,000 inhabitants. Human presence in Mixteca Alta (circa 3400–3500 years BP) has been established by radiocarbon dating of soil organic carbon present in agriculture terraces known locally as *lamabordos*. Traditional agriculture based on terraces has been ongoing ever since.

Nowadays, population density and demographic growth are low. Because of lack of economic opportunities, emigration to urban areas is significant. Following migration, terrace maintenance has become increasingly difficult and abandonment is widespread in the area. However, traditional agriculture in the geopark can still feed the local population. Terracing has proved efficient in adjusting cropping to changing climatic conditions, particularly a decrease in rainfall and varying onset of the rainy season (Orozco-Ramírez et al., 2019). A variety of maize has been adapted to terrace conditions by the *cajete* farming system, a traditional practice that uses residual soil moisture (Figs. 2–4).

Concluding remarks

Traditional agricultural terracing is a prominent cultural landscape worldwide. Developments in disparate places suggest multiple origins in different environments and cultures, indicating a complex human-environment relationship through history. These systems have proved efficient in terms of sustainable agricultural practices, especially small scale rain fed farming developments in mountainous tropical developing countries.

Devoted to subsistence agriculture, terraces can feed large populations under various political and organizational systems. Abandonment has also been occurring in different places throughout history, probably accounting for the decline of terracing at most sites. Despite differences in the type of human-environment relationship, abandonment seems to follow economic crises in agriculture which in turn triggers migration. Thus, maintenance of terrace structures as well as the human power required to perform farming activities becomes impractical.

Interest in terracing and the chance to overcome the challenges posed by modernization is increasing. In 2010, the International Terraced Landscapes Alliance (ITLA) was founded to recover the memory of the terraces as landscapes of the culture of their inhabitants. Joint interest by academic groups and social organizations is expressed in the biannual celebration of international

congresses that discuss the past, present and future of terrace landscapes. These efforts recognize the problems but also the potential of terrace farming when humans at large face crucial problems in the rural domain. Maintaining terraces is an important aspect of food security and human health.

Abstract

Soil quality and environmental protection necessitate ground-level policy and legal frameworks, followed by strict and appropriate planning, execution, and regulatory reforms on a time-to-time basis, in accordance with the requirements and situations for soil management. Soil quality and protection of the environment have received international recognition in the policy arena. There is an urgent need to strengthen our knowledge and initiate action to protect soil quality as the soil is considered a living body. This chapter helps to provide a roadmap to feasible plans, and policies to protect soil quality by including them as part of land-use planning. Therefore, governments should encourage and incentivize farmers to enhance eco-friendly land management technologies and soil ecosystem services.

Key points

- Contributes to the protection, restoration, and enhancement of soil organic carbon for landowners.
- Land management technologies and soil ecosystem services should be encouraged and incentivized by governments.
- Enhancing soil quality through existing value chains, policy frameworks, and financial mechanisms.
- Environmental protection and soil quality must receive an international recognition.

Introduction

Soil is a living body that offers several ecosystem services for humans (Wall and Nielsen, 2012). It provides underlying support for the economy and society. Soil has been exploited continuously for hundreds of years. Since the green revolution in the 1960s, the exploitation of soil for food production has intensified and this is likely to increase further in the future with increasing population and food requirements. A global ecosystem loss of US\$ 6.3–10.6 trillion was estimated in 2017 due to soil degradation, which was equivalent to 10–17% of the *gross domestic product* (GDP) (Land and Soil Policy, 2019). Every year, erosion leads to the loss of 25–40 billion tonnes of fertile topsoil, which significantly reduces the soil's ability to store and maintain carbon, water, and nutrients. This ultimately causes loss of crop yield and food quality. An estimated 766 million tonnes of cereal production is lost every year due to soil erosion. Further, if action is not taken in time to improve soil quality, over 253 million tonnes of cereals are projected to be lost globally due to erosion and poor soil quality by 2050. As a result, an estimated 1.5 million km² of cropland would be removed from production, which is roughly equivalent to the intensively cultivated arable land of South Asia (Land and Soil Policy, 2019).

Presently, the United Nations (UN) defines the “Sustainable Development Goals (SDGs)” with well-defined indicators and targets leading to the overall sustainability of the Earth ecosystem in all respects or spheres of human society. Soil quality and environmental sustainability can be accomplished through the adoption of eco-friendly technologies and measures by the farming community and stakeholders that lead to harmony in resource use and ecosystem services.

Soil quality should be managed by adopting sustainable agricultural practices such as crop diversification, maintaining constant vegetative ground cover, adding crop waste, reducing the use of pesticides, avoiding tillage, etc. (Sherwood and Uphoff, 2000). The conservation and protection of soil may contribute directly to climate change resilience, and thus are critical for providing food,

water, and energy for humanity. Globally, several countries have initiated action plans to prevent the deterioration of soil quality and to enhance the sustainability of natural resource use.

On an international scale, various programs and schemes for preventing soil erosion and protecting soil quality have been implemented. Therefore, it requires appropriate land and soil policies with increased attention to the soil as a major sink for carbon accumulation and thus its direct contribution to climate change mitigation. The formulation and implementation of effective policies are required at the national level for restoring and maintaining soil quality by farmers who can be incentivized for positive environmental outcomes on the basis of soil tests. Simultaneously, there is a need to strengthen further the research, development and extension network which needs serious attention by the policymakers.

This chapter will help in implementing and promoting the policies, plans and thrust areas to restore and protect soil quality by including them in land-use planning. In this planning, many sectors will have to come together and contribute to meet common goals, such as food supply, water supply, and conservation of biodiversity. Therefore, the government should encourage and incentivize farmers, who are the main link in this context, to adopt eco-friendly land management technologies for healthy ecosystem services. Likewise, small and medium agribusinesses engaged in sustainable land management should also be supported by governments.

Soil protection legislation and regulations: A global perspective

The existing policies or legislation are specific to a particular aspect of soil and its functions. Therefore, they do not constitute a coherent soil protection policy because they do not apply to all soils and do not deal with all threats to soil quality. However, current policies reflect a wide dimension and address various issues and areas related to the sustainable management of soil resources.

Recently, there has been increasing awareness of the importance of sustainable soil management with the implementation of legislation and regulations for adopting improved soil management practices and limiting soil losses, globally. Following the International Year of Soils in 2015, the International Union of Soil Sciences (IUSS) declared the International Decade of Soils (2015–2024) to continue raising awareness about the significance of soil for life (IUSS, 2016). During this time, the IUSS Executive Committee and Council are playing a critical role in determining overarching goals and directions (Fig. 1) (IUSS, 2016).

The United Nations has included sustainable soil management (SSM) in the SDGs to set new global benchmarks for soil management. The SDGs such as SDG1 (no poverty), SDG2 (zero hunger), SDG3 (good health and well-being), SDG6 (access to clean water), SDG7 (affordable and clean energy), SDG11 (sustainable cities), SDG12 (responsible consumption and production), SDG13 (combating climate change), and SDG15 (life on land) draw attention to the need to protect soil quality and improve degraded soils (Fig. 2) (Policy Brief, 2019). In 2012, the UN General Assembly initiated the Global Soil Partnership (GSP) under the Food and Agriculture Organization (FAO) to promote soil protection, conservation, and productivity (Policy Brief, 2019). In 2016, the GSP and FAO published the Voluntary Guidelines for Soil Sustainable Management (VGSSM), an attempt to define Sustainable

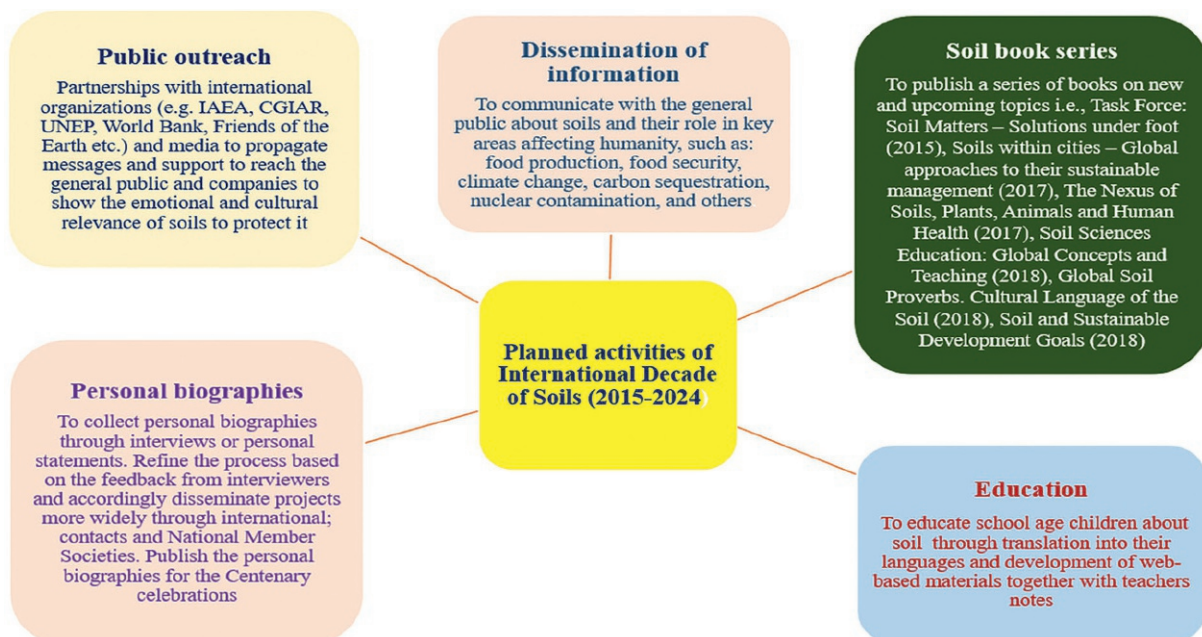

Fig. 1 Planned activities of the International Decade of Soils (2015–2024); CGIAR: Consultative Group on International Agricultural Research; IAEA: Consultative Group on International Agricultural Research; UNEP: United Nations Environment Programme.

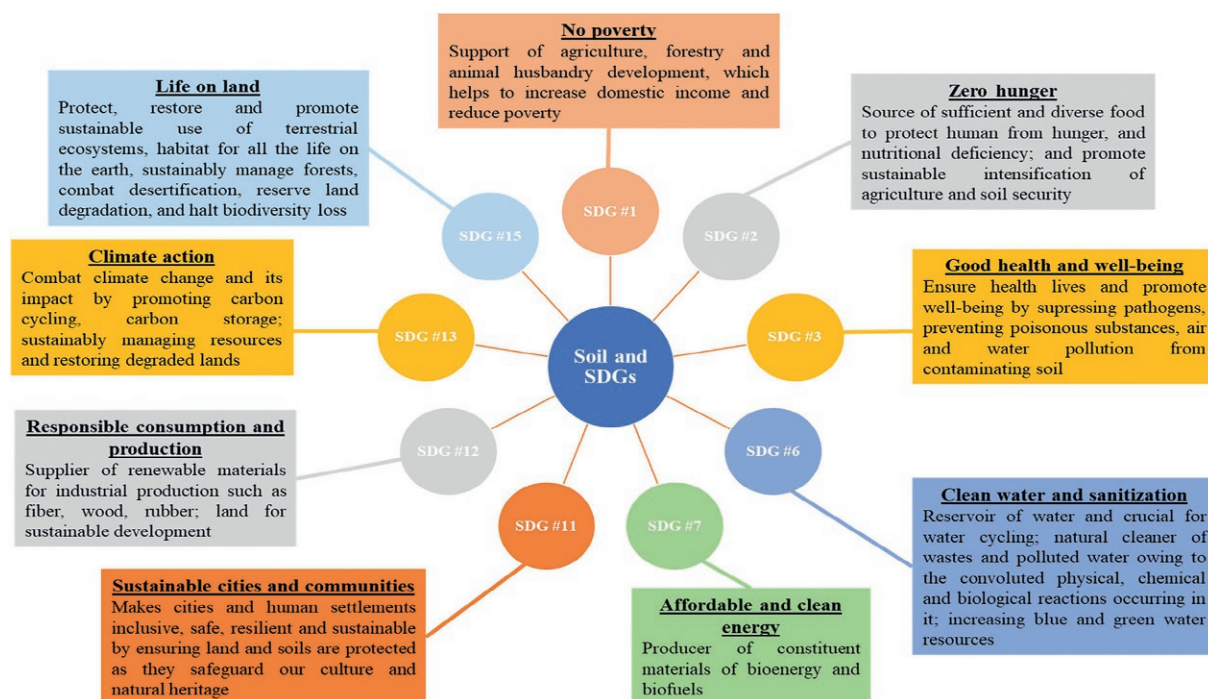

Fig. 2 Soil and Sustainable Development Goals (SDGs).

Soil Management (SSM) practices at the global level (Policy Brief, 2019). The FAO and its member countries are supporting the policies and legislation for improving global soil governance for the last decade (FAO and ITPS, 2015).

Soil quality is a global concern that has been mentioned in three international treaties, which contain relevant provisions on soil protection: UN Conventions, i.e., the Convention to Combat Desertification (UNCCD) of 1994, the Framework Convention on Climate Change (UNFCCC) of 1992 and the Convention on Biological Diversity (UNCBD) of 1992 (IUCN, 2018). The main purposes of the UNCCD are to combat desertification and mitigate the effects of drought. The UNCBD includes the preservation and sustainable use of biological diversity for soil and terrestrial ecosystems. The UNFCCC focuses on adaptation and mitigation actions, which include sinks and reservoirs of greenhouse gas emissions (GHGs).

As a result of the great efforts of international agencies and unions, in the last few years several laws, acts, regulations and legislations have been enforced and others are under consideration across several regions and countries. For example, the United Nation's soil Principles, EU Soil Policy for 2030 (Table 1), soil protection legislation and regulations of Greece (Table 2) and the United States (Tables 3–5).

Table 1 Soil protection laws of European Unions (European Commission Published a Policy Report, 2006)

Law/framework	Directive/regulation	Ways in which it helps to protect soil
Environmental Liability Directive	Directive 2004/35/EC	Sets most appropriate measures to remediate land damage
Industrial Emissions Directive	Directive 2010/75/EU	Ensures the operations to ensure soil quality
Environmental Impact Assessment Directive	Directive (85/337/EEC)	Identify, describe and assess the direct and indirect environmental impacts including land
Sewage Sludge Directive	Directive (86/278/EEC)	Encourage and regulate the use of sewage sludge in agriculture to prevent their harmful effects on soil quality
Regulation on fertilizers	Regulation (EU) 2019/1009	Regulates thresholds for contaminants, and presence in fertilizer products, particularly cadmium, to minimize soil pollution
Land use, land-use change and forestry Regulation	Regulation (EU) 2018/841	Sets a commitment for each Member State to ensure that GHG (greenhouse gas) emissions from land use are accounted for
Common Agriculture Policy (CAP) Implementation of soil management measures and associated obligations to advance soil protection in both agricultural and forestry systems	Regulation 1307/2013	and regulation 1306/2013
EU Biodiversity Strategy for 2030	–	Support the recovery of nature, limits soil sealing; restore degraded ecosystems, in particular, soil; protect soil fertility, and reduce soil erosion and the over-use of nutrients

Table 2 Regulations and legislation for soil protection in Greece.

<i>Laws/Action Plans</i>	<i>Theme</i>
Environment Protection Law (1986)	Soil erosion, conservation and salinization/sodification

Table 3 Soil health protection acts and programs enforced in the United States (USDA, 2022).

<i>Act/program</i>	<i>Action for soil protection</i>
Soil Conservation and Domestic Allotment Act (1936)	The government pays farmers to reduce production to conserve soil and prevent erosion
Soil and Water Resources Conservation Act (1977)	Providing broad strategic assessment and planning authority for soil conservation and natural resources management
Environmental Quality Incentives Program (EQIP)	Providing financial and technical assistance to agricultural producers to address natural resources and soil management
Conservation Stewardship Program (CSP)	Helps agricultural producers maintain and improve their existing conservation systems and adopt additional conservation activities to address priority resource concerns, particularly soil
Agricultural Conservation Easement Program (ACEP)	Helps landowners, land trusts, and other entities to protect, restore, and enhance wetlands, grasslands, and working farms and ranches through conservation easements
Healthy Forests Reserve Program (HFRP)	Helps landowners to restore, enhance and protect forestland resources through easements and financial assistance to enhance carbon sequestration and others

The United Nations Global Compact facilitated the development of “Soil Principles” for sustainable soil management. Soil principles aim to increase the understanding of key actors to protect soils through long-term programs, and to strengthen existing policies for soil conservation:

1. Protect soil from physical, chemical and biological degradation, limit erosion and avoid deforestation.
2. Restore soils on degraded, stranded and marginal lands.
3. Maintain soil-based ecosystem services, water availability and quality.
4. Enhance soil productivity according to its natural capacity.
5. Develop extension services, and knowledge systems, and promote innovation.
6. Communicate the importance of soil.

These principles are the framework for collaboration between the United Nations, governments, companies, civil society and other stakeholders. They offer a framework of outcomes and actions for companies to align with the SDGs and Agenda 2030. To support these principles, the UN Global Compact encourages companies to commit to global soil quality, share and promote better soil management practices, including soil quality in strategic planning, and work in partnership with stakeholders to ensure healthy

Table 4 State-wise legislation in the United States (Soil Health Institute, 2022).

Bill	Bill No.	State
California's Healthy Soils Initiative (HSI) (Agricultural Lands: Greenhouse Gases: Healthy Soils Program)	SB.1350	California
Agriculture Climate Adaptation Tools Program	AB.409	California
Environmental Farming Incentive Program	SB.253	California
An Act Establishing A Regenerative Agriculture Program	HB.06647	Connecticut

Farmer Apprentice Mentoring Program; Whole Farm System; Appropriation	HB.1505, SB.1544	Hawaii
Property Tax Exemption for Agricultural Land planted in Cover Crops	HSB.78, SSB.1123	Iowa
An Act for a State-wide Soil resource health and monitoring system	HF.102	Iowa
A bill for an act creating an agricultural land, soils, water quality, and farm tenure initiative committee	HF.103	Iowa
An Act requiring water quality plans for persons receiving financial assistance for establishing soil and water conservation plans	HB.406	Iowa
Amends the Soil and Water Conservation Districts Act	HB.2737, SB.1980	Illinois
Amends the Department of Natural Resources Act	HB.2819	Illinois
For legislation relative to storm water management and climate change adaptation incentives. Revenue.	SB.1663	Massachusetts
An Act to promote healthy soils and agricultural innovation within the Commonwealth	H.873, S.438	Massachusetts
An Act promoting healthy soils for reducing greenhouse gases and the effects of climate change in the Commonwealth	S.2402	Massachusetts
Maryland Healthy Soils Program	HB.1063	Maryland
Agriculture—Cost-Sharing Program—Fixed Natural Filter Practices	HB.687	Maryland
Agriculture—Maryland Healthy Soils Grant Program	HB.1176	Maryland
A resolution to declare April 28-May 5, 2019, as Soil and Water Stewardship Week in the state of Michigan.	HR.0084	Michigan
Working lands drinking water protection pilot program and appropriation	SB.1637	Minnesota
Drinking water protection pilot program established, and money appropriated.	HF.1569	Minnesota
Board of Water and Soil Resources Soil Health state-wide action plan funding provided and money appropriated	SF.1418, HF.1609	Minnesota
Create the Healthy Soils Task Force and add a Use for a Fund	LB.243	Nebraska
Adopt the Soil Health and Productivity Incentive Act	LB. 729	Nebraska
Provide for a climate change study	LB.283	Nebraska
Healthy Soil Act	HB. 204	New Mexico
Soil & Water Conservation District Day	SM.75	New Mexico
Carbon Farming Act	SB.4875	New Mexico
Green New Deal	A05334-A	New York
Oklahoma Carbon Sequestration Enhancement Act	HB.1192	Oklahoma
Relating to greenhouse gas emissions; declaring an emergency.	HB.2020	Oregon
Relating to greenhouse gas emissions; prescribing an effective date.	SB1507 A	Oregon

Table 5 Soil protection legislation introduced recently in the Senate and House of the United State (<https://www.congress.gov/bill>).

Legislation	Actions for soil protections
Healthy Soils Healthy Climate Act (2021) (amendment to the Food Security Act of 1985)	Create permanent payments within the environmental quality incentives program for soil health practices and carbon sequestration
Healthy Soil, Resilient Farmers Act (2020)	Facilitating soil health transition loan and soil health transition plan
Study on Improving Lands Act (2021)	Direct a study on the state of soil health on federal lands that determine impacts such as grazing, wildfire, recreation, and invasive species
RESTORE Act (2021)	selection of forest landscape to conduct a forest landscape project on specified management activities, including restoring soil health
Farmers Fighting Climate Change Act (2021)	This bill expands the Conservation Stewardship Program of the USDA to provide for the establishment of climate change mitigation and reduce GHGs emissions
Future of Agricultural Resiliency And Modernization Act (2021)	Award grants to carry out projects that reduce GHG emissions, improve soil health, and increase carbon sequestration
Naturally Offsetting Emissions by Managing and Implementing Tillage Strategies Act (2021) (amendment to the Food Security Act of 1985)	To optimize the sequestration of carbon and the reduction of net GHGs emissions in agriculture systems
Agriculture Resilience Act (2021)	To address the impact of climate change on agriculture, and for other purposes including soil quality
Climate Stewardship Act (2021)	To provide incentives for agricultural producers to carry out climate stewardship practices, to provide for increased reforestation across the US
BIOCHAR Act (2021)	To establish a biochar demonstration project and biochar grant program to promote soil health

soils. When viewed in the wider context of Agenda 2030, companies that support the Soil Principles will catalyze investment and action in support of the world's soils and contribute to the implementation of SDGs.

The EU's soil policy for 2030 establishes a framework for protecting soils and ensuring their sustainable use. To accomplish this vision, three major objectives were set: (i) all EU soil ecosystems should be healthy and resilient and continue to provide core services; (ii) there is no net land taken and soil pollution is reduced so that it is no longer harmful to people's health or ecosystems; and (iii) soil protection, restoration, and sustainable management are common practices. To attain these targets, the strategy emphasizes some of the key targets:

- Submitting a separate legislative proposal on soil health by 2023 to support the goals of the EU soil strategy to achieve healthy soil by 2050.
- Making sustainable soil management the new standard by providing a plan for farmers to have free soil testing, and encouraging sustainable soil management through best management practices and common agricultural policy (CAP).
- Reclaiming eroded soils and cleaning up contaminated areas.
- Preventing desertification through the development of a uniform approach for assessing it and land degradation.
- Consider establishing legally enforceable targets to prevent the draining of organic soils and wetlands and restore drained and managed peat lands to adapt and militate against climate change.

At the EU level, there was no binding overarching framework that strategically defined policy priorities or parameters for soil protection. Soil protection outcomes are mostly derived from other laws delivering environmental objectives and are not explicitly soil-focused, as follows.

Programs and acts for agricultural waste management

The continuous growth in the world's population has raised the demand for food and increased agricultural production, which results in the generation of tons of agricultural waste at a global level (Sabiiti, 2011). Agricultural waste includes materials generated by various agricultural activities including crop residues (leaves, residual stalks, husks straw, roots, shells, etc.), manures, wastes from slaughterhouses and poultry houses, runoff, and leaching of fertilizers, pesticides and silt drained from fields, and processing residues including husks and domestic waste (e.g., skins of fruits) (Fig. 3).

The improper disposal of agricultural waste has adverse effects on the environment, therefore, its recycling and reuse can help in protecting the environment (He, 2019). The proper management of crop residue can generate bioresources such as organic fertilizers for farming communities which helps to boost soil quality. These organic wastes are rich in organic carbon, nitrogen,

Fig. 3 Agricultural waste.

phosphorus, potassium, and other beneficial micronutrients that improve soil structure and fertility to a certain extent. In addition, it encourages efficient energy use of agricultural wastes. These waste products can be used for biocomposting, which can provide organic manure to protect soil from deterioration. With proper planning, public awareness, and implementation of government policies and laws, agricultural waste can be managed and used properly to generate beneficial bioresources (Sabiiti, 2011). Policies are needed to raise awareness of the public and farmers to these benefits. In addition, this also calls for the setting up organizations or institutions to harness agricultural wastes as a potential resource in farming and energy production (Sabiiti, 2011). In recent years, the management of agricultural wastes has become an issue of concern for policymakers to ensure ecological agriculture and sustainable development. There is a need to focus on policies and regulations to recycle agricultural solid waste efficiently into useful products to generate new income and employment opportunities (Wang et al., 2016). This will require better use of technology and incentives, a change in philosophy and attitudes, and better approaches to agricultural waste management. Government initiatives such as subsidies, encourage agriculture-linked enterprises and cultivate service entities, etc. that can save resources, develop the economy, and protect the environment by increasing and improving the recycling of agricultural wastes (Wang et al., 2016).

The benefits of crop residue management and the adverse effect of residue burning on soil quality need to be understood by farmers through training to ensure soil quality. In South Asian countries, governments should implement effective strategies for in-situ crop management at the time of rice harvest to use the waste (Meena et al., 2021). This may include initiatives to create awareness, support for machinery required, scientific guidance, and the strict enforcement of rules and regulations by local administrations (Fig. 4). In addition, nexus thinking in environmental management is an emerging concept that can be beneficial to governments and other sectors of society. The concept of nexus thinking promotes stakeholders' involvement and integration at a higher level, going beyond disciplinary boundaries, which could provide a benchmark for resolving issues like residue burning. Efforts are required at all levels, including basic and strategic research, technology dissemination, strengthening stakeholder links, financial support, policy formulation, and implementation.

Action plans for policymakers and planners

The task for framing effective soil policies toward sustainability is difficult to formulate and implement. It requires assessment of soil quality indicators and properties, soil functions, land capability classification, land use, etc. to develop policies for managing the soil ecosystem (Fig. 5). Further, technologies such as low input agriculture, organic farming, and precision farming would benefit soil quality by optimizing the use of fertilizer and nutrient cycling within the agroecosystem to maintain soil quality. From a policy perspective, optimum fertilizer use should be given major emphasis to promote soil quality. Management schemes and plans should be implemented at the local, regional, and national levels, depending on soil and local conditions. Above all, the main

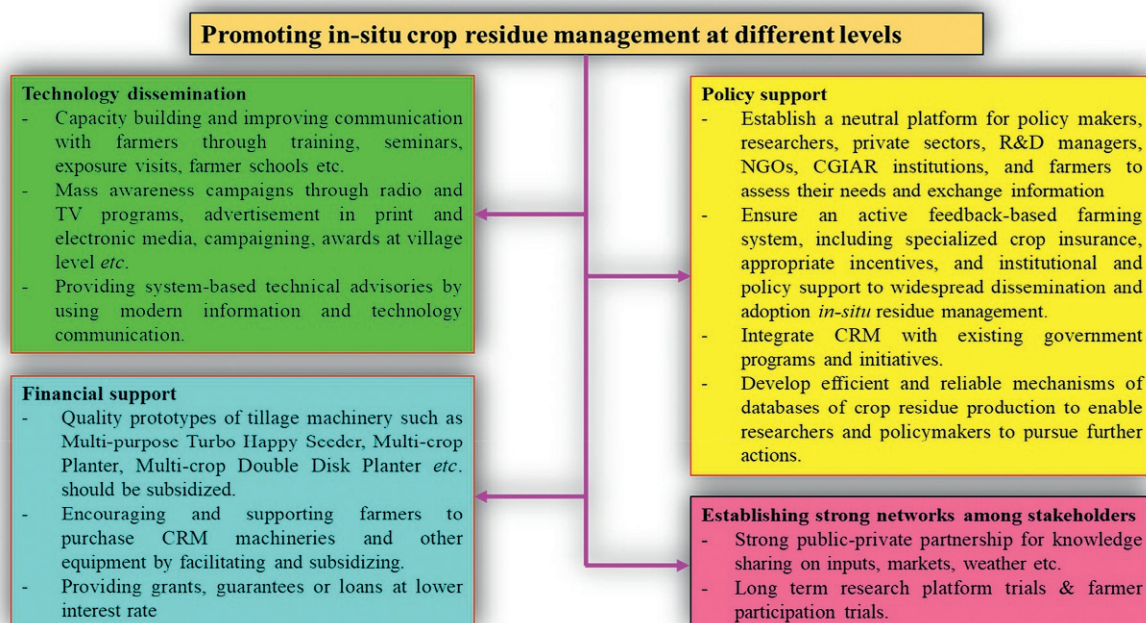

Fig. 4 Plans and policies for in-situ crop residue management (CRM). CGIAR: Consultative Group on International Agricultural Research; NGOs: Non-governmental organizations.

Fig. 5 Action plans for policymakers.

action plans should include the reduction of land loss and restoration of degraded land, should promote reasonable access to land and secure land tenure, and enhance capacity-building, technology transfer and financial support by various methods (United Nations, 2009).

i) Reduce land losses and restore degraded land

- Find interrelationships between climate change, land degradation, and desertification, including the need to promote integrated land, and water management to address various issues;
- Support sustainable land management by increasing soil and water productivity, and improved security of tenure for people living in vulnerable areas;
- Protect land resources sustainably using scientific and indigenous knowledge;
- Encourage the improvement and restoration of degraded lands by integrating pastoral and agricultural land use, as well as best management practices;
- Address the risk of erosion and land losses caused by sea-level rise, particularly in low-lying coastal states and areas, by planning land-use access and adaptation programs for climate change;
- Control soil erosion and enhance soil water holding capacities through sustainable forest and agroforestry management;
- Promote national action plans and international cooperation to prevent the spread of sand dunes, and reduce the severity and frequency of sandstorms by strengthening early warning systems, restoring vegetation, and supporting rural community initiatives in affected areas, primarily in developing countries;
- Encourage appropriate well established practices and indigenous knowledge concerning land use, water management, and farming activities;
- Converge sectorial policies and programs at the national level to stop and reverse land degradation and create coordination through convergence.
- Improve cooperation and coordination between the authorities that manage land and water resources;
- Strong support for policies aimed at reducing land degradation while also creating jobs and contributing to the eradication or elimination of poverty in developing countries;
- Protect and conserve soil and land resources through land use, spatial planning, and sustainable agricultural practices such as agroforestry, eco-farming, diversification, reduced tillage, perennial vegetation-based land cover, and enhancing capacity-building for sustainable development of peoples;
- Develop land management policies that address the direct and indirect causes of land degradation, such as erosion, salinization, alkalization, desertification, pollution, and loss of SOM.
- Adopt policies that will restore the soil's physical integrity, improve the nutrient status, and increase SOM content;
- Strengthening capacity, especially in developing countries, for monitoring soil quality and land degradation, including looking for and evaluating the information on biophysical and socio-economic perspectives of land degradation.

- Ensure a proper balance between social, environmental, and economic aspects of sustainability, livelihoods, and food productivity in land management and policies;
 - Encourage inventory, assessing, monitoring, and understanding of the potential of land to support ecosystem functions, including creating a global soil map with the help of local and indigenous knowledge systems, and accordingly, include long-term strategies in land-use planning for soil management;
 - Empower local authorities to execute sustainable land policies consistent with local conditions and national priorities;
 - Build partnerships and networks among the stakeholders in land-use planning and management to gain a better understanding of land-related issues by considering sustainable goals and indigenous knowledge to enable land development and identify potential areas for conservation;
 - Provide financial assistance to encourage private and public investments in research and development for sustainable land management, combat land degradation and ensure land managers' access to credit;
 - Encourage initial start-up at the small scale for resource-constrained smallholders to acquire and adopt sustainable land management practices and technologies;
 - Establish a new center of excellence and renovate the existing centers as part of land policy, tenure, and land management;
 - Establish the set of norms and standards for a proper review, monitoring, and evaluation of land policies and their indicators.
- ii) Promote reasonable access to land and secure land tenure
- Promote soil and water conservation by ensuring land tenure security for rural land users, particularly women, indigenous people, and other vulnerable groups;
 - Establish cost-effective and efficient land administration systems, including transparent tenure and registration systems, that may contribute to investment and best land management practices, using the latest information technologies;
 - Recognize different laws and or systems that govern land access and tenure among states, improve institutional and legal frameworks for the administration of property rights and tenure systems considering smallholder farmers, established land tenure, rural poor, customary tenure, and local practices; and adopt laws and policies that promote equitable and secure access to land and tenure for the poor, especially women, indigenous people, and other marginalized groups;
 - Establish a mechanism for the dissemination of additional knowledge and information on land rights and implement civic education campaigns to educate the public;
 - Recognize rights for other uses such as grazing and wood gathering, which often contribute to women's livelihoods;
 - Allow and promote a more equitable role for women in land-use planning and management decision-making;
 - Eliminate the obstacles to the full understanding of the rights of the people living under colonial and foreign occupations, which are incompatible with the dignity and honor of a human being and therefore need to be removed.
- iii) Enhance capacity-building, technology transfer and financial support

Capacity-building, training, and development of skills for soil quality management should be integrated with the advancement of new techniques and tools. Proper research, development, and extension activities enhance the various governmental schemes, plans, and policies among farming communities. Training and extension activities need to be carried out at the grassroots level among farmers in terms of generating awareness about the soil resources together with positive outcomes of adopting various eco-friendly technologies. Government policies must be aligned with farmers' varying priorities and needs (Katyal et al., 2016). Further, the improvement and establishment of a knowledge base on soil technology and sustainable agroecosystems are linked with innovation, research, and development by involving interdisciplinary approaches. This would lead to the identification and screening of key environmental datasets that underpin the ecological and environmental perspectives and their sustainable management for human civilization (Kumar et al., 2015). The key action plans for capacity-building and enhancing technology adoption among farmers are given below:

- Strengthening the scientific base and advancing research on drought and desertification for making informed decisions on land management, and measuring and monitoring the impact on programs to control the deterioration of soil quality;
- Develop appropriate technologies for assessing, analyzing, and quantifying the consequences, impacts, and remedial options of deteriorated soil quality and desertification.
- Support for developing nations based on mutual terms through sharing and scaling up of advanced science-based practices and technologies, including best management practices and practical experience in combating land degradation and desertification. For example, sustainable agriculture practices and vegetation conservation or rehabilitation can serve advanced science-based practice together with management.
- Strengthening investment in land management to encompass sustainable forest management and land-use planning to improve soil quality and restore degraded land in arid, semi-arid, and semi-humid environments.
- Encourage and invite developed nations and the Global Environment Facility Council to provide adequate, consistent, and timely monetary support to areas affected by land degradation;
- Provide financial assistance to implement reform of land tenure in developing nations and countries in transition to promote sustainable land use, efficient governance, comprehensive planning, and equitable access to land;
- Encourage countries, particularly developing countries, to improve their scientific understanding of land resource systems by strengthening their technological capacities, including, as appropriate, supporting pilot projects to test their research findings;
- Enhancing human resource capacity through educating and training people for effective land management, particularly in developing nations.

Even after policy formulation, coordination among stakeholders needs to be improved to achieve efficient policy implementation and outcomes. Further, uptake could be achieved through need-based continued advice, information support, monitoring, and unpaid partnership. So, policies should encompass effective regulation and partnerships since land is usually privately owned and cannot be protected by the government alone. For that, farmers, land managers, local bodies, bureaucrats, policymakers, developers, researchers, and construction companies must work together under an umbrella to address diverse issues to promote healthy soils. Technology demonstration for awareness and popularization of soil quality management practices through public-public, public-private, and public-private-producer and private-private partnerships assures the successful implementation of processes at their level (Fig. 6).

A soil framework must be established for future policy development as well as to assist in monitoring and evaluating soil plans in order to strengthen the partnership with government, private agencies, and stakeholders. In the process of policy development and evaluation of its effectiveness, effective monitoring provides critical evidence on the state and changes of our soils (DEFRA, 2009). This will facilitate a more effective exchange of information, in particular for the advancement of soil research. A Soil Framework has to be developed in conjunction with advice from key stakeholders, keeping in mind that soil is a vital part of our economy, environment, and heritage, which needs to be protected for current and future generations. It should aim to promote the sustainable management and protection of soils through effective monitoring and evaluation of soil plans that are consistent with the economic, social, and environmental needs of the country. The following 13 activities are identified as being vital parts of this framework (The Scottish Government, 2009):

[illegible]

Fig. 6 Farmer-centric policy implementation.

Financial incentives-A need for supportive interventions

All benefits must be monetized to determine whether or not sustainable farming practices will deliver an appropriate return on investment at the farm level. A higher net income in farmers' fields can be achieved by improved marketing of farm products, reduction in the cost of cultivation, direct payments, subsidies, and insurance (Klauser and Negra, 2020). A combination of all these incentives can reduce barriers to the implementation of improved land management practices and facilitate farmers' adoption of them. Also, to remove barriers to the adoption of soil health-promoting practices, agricultural developmental activities need to be carried out together with policy and financial interventions adapted to specific conditions. While designing agricultural developmental activities, it should also be considered that there are still a significant number of farmers who do not have adequate resources, inputs, risk tolerance capacity, knowledge, and assets needed for the adoption of soil health-promoting activities. To increase the rate of adoption of these soil-health promoting activities among smallholders, these practices should be designed considering the local and regional conditions, agronomic variables, and policy framework context.

When soil health-promoting activities enable yield improvement or reduce production costs, there is a strong incentive for their adoption, and only help to facilitate them will be required. In the case of delayed agronomic benefits, smallholder farmers will not be sufficiently encouraged to adopt new farming practices until additional support is provided to offset new costs and the risks involved. A temporary or permanent subsidy (i.e., carbon offset payments) may be required for smallholders to adopt soil health-promoting practices when their environmental benefits extend beyond the farm. A farmer's income can be increased through increased yield owing to the adoption of improved production practices and the accrual of environmental benefits in the form of finance, subsidies, premium markets for agricultural goods, or payments for ecosystem services. Current policies and financial systems do not provide enough financial incentives to smallholders for implementing better soil management practices, therefore, fiscal support is needed in many cases.

Well-designed subsidies, land registration, and effective crop varieties are some of the fundamental elements of an enabling policy environment (WBCSD, 2018). For example, government subsidies or philanthropic funding can create multiple types of support for smallholders, such as soil amendments, customized fertilizers, and crop varieties in rotations that improve soil health. Governmental subsidies can include financial support for technical support and setting up marketing infrastructures such as storehouses, credit registrations, and price information (McCann et al., 2018).

There are several well established and new financial plans and strategies for smallholder production systems to incentivize farm-level contributions to climate change mitigation. Smallholder production has not yet demonstrated the feasibility of some newer approaches for achieving environmental security. An appropriately designed credit, loan, or insurance scheme that bridges the gap to an immediate return on investment could enable smallholders to follow soil-health promoting practices. Value chain finance could be provided to smallholders such as insurance, receivables financing, and pre-financing (Havemann, 2016). Farm credit targeted to smallholders often requires novel risk screening and collateral requirements allowing appropriate interest rates without credit histories or assets.

Soil health-related interventions are crucial for developing well-conceived fiscal structures/strategies and other specific arrangements because their success relies on agronomic yield and environmental benefits. Debt-based financing policies could increase the farm-level risk if they are not harmonized with the farmer's capability to repay loans. It is therefore important to follow debt instruments with approaches that enhance market value (such as higher market prices, Payment for Ecosystem Services—PES) or reduce their net costs (such as access to affordable, high yielding seeds). Several schemes for carbon credit and PES have been designed and tested to enhance the return on investment of improved adoption of management practice (Henderson et al., 2018). A program on PES can help land managers earn additional income generated by the adoption of sustainable land management practices and technologies. To ensure the success of the program, a strong network of local and national institutions is needed to ensure land tenure and an effective market-based payment mechanism. For instance, the Forestry Act (1996) of Costa Rica allows land users to be compensated for ecosystem services provided off-farm through forest conservation certification. As a result, deforested lands have been successfully restored through the effective implementation of natural resource management practices.

For PES to work, there must be buyers willing to pay for environmental services (for example, development finance institutions, businesses emitting GHGs, and water supply activities), and it depends on the establishment of low-cost monitoring and transaction instruments. Farmers can receive direct monetary support (usually through an aggregating entity) to adopt specific practices for a set period of time (i.e., payments on a unit area basis) or payments for environmental performance (i.e., carbon

sequestration). In addition, the differences in methods used as well as the high cost of assessing environmental performance at the farm level (such as carbon stocks and water quality) have hindered PES approaches. Prices for agricultural carbon credits have been low and volatile as a result of inconsistencies in soil carbon sequestration and benefits accruing from new practices, and poor agreements about the eligibility and permanence for compliance schemes (Meena et al., 2022).

The majority of smallholders in developing and underdeveloped countries do not have access to financial incentives that deliver improved environmental outcomes, such as lower costs for agricultural loans and PES schemes. Smallholder farming systems are fragmented, and the sustainability and scalability of PES initiatives depend on reliable metrics, and transaction costs (Salzman et al., 2018). Philanthropic, public and private sources will probably combine to supply finance for testing interventions and creating new arrangements for smallholders in the short term. The funding for such initiatives may be provided in the form of blended finance, whereby structured vehicles combine sources of funding for specific goals under particular objectives, or simply mobilize funds from a variety of sources to support certain interventions in a coordinated way. In the long run, the financing needed to continue new value chain activities is likely to be financed mainly by the private sector (such as value chain companies or commercial banks) or from public loan programs.

Investment to improve soil quality can only produce value at the farm level if the agronomic practices promoted, either individually or collectively, bring about augmented profitability for the short term. The benefits of soil health-promoting practices (i.e., improved crop yield and resilience, abridged production costs) can be converted into near-term return on investment, if required inputs, equipment, and knowledge are utilized effectively.

Financial assistance can be provided to farmers for:

Managing land to maintain, restore or promote natural heritage and environmental sustainability.

Managing land to adapt to and mitigate climate change

Managing land to avert, reduce or protect from environmental risks

Improving or protecting the quality and health of soil and plants

Conserving natural resources, habitats, and biodiversity

Starting or improving the productivity of agricultural, horticultural, or the forestry system in an environmentally sustainable manner

Encouraging food production in an environmentally sustainable manner

Financial assistance for promoting these kinds of activities among farmers may be given:

In the form of, among others, grants, loans, or guarantees

Subject to conditions the government considers appropriate, which may include the provisions under which financial assistance is to be repaid or otherwise made good (with or without interest)

To a person connected to a third-party scheme made or operated by that person

In the form of subsidies for farm inputs and machinery that promote the agenda of sustainable land management.

Overall, we can progress toward the improvement of soil quality through existing value chains, policy frameworks, and financing mechanisms. Demand-driven, network-based research and development and technology transfer can cater to cross-value chain interventions together with co-investment partnerships (e.g., with off-taker companies, input suppliers, insurance companies, financial institutions, and traders). Over the past few decades, the CGIAR (Consultative Group on International Agricultural Research) and its partner countries have built a significant body of research on soil aspects. A continuing and prolonged investment is required to advance quantification and prognostic capacity concerning the relationship between investment in strengthening smallholder capacity, changes in soil quality, and improvements in soil management as well as changes in risk and resilience at the farm and community levels. Farm management options can be tested and validated through research and development and scaling efforts in partnership with organizations committed to building farmer capacity.

Private organizations for investment in soil quality and environmental protection

Increasing carbon sequestration would help to maintain or improve soil quality while also reducing emissions and mitigating some of the negative effects of climate change. Investment in soil quality and environmental protection varies as per the interests of private organizations, either to maintain or increase their revenue, to reduce or avoid the costs of their products, to gain reputation, or to open up new financial opportunities (IUCN, 2018). Hence, to achieve the desired outcomes like increased productivity, preserving biodiversity, and environmental conservation, science-based solutions should be piloted and implemented. Recently, with increasing consumer awareness, several global companies have realized the importance of investing in soil quality and environmental protection for the future of their business. Healthy soil and better environmental conditions increase crop productivity, with more secure supply chains and better prospects to meet the global food needs of the growing population (IUCN, 2018).

Several large companies are committed to reducing carbon emissions significantly and promoting actions that will lead to augmented sustainability in agricultural systems. For example, DANONE Inc. has begun a program to become carbon neutral by 2050, which will influence the farm management programs in Belgium (DANONE, 2021). The Nature Conservancy (TNC), a global organization with headquarters in Arlington, Virginia, USA, has funded five new private enterprises that have potential in key areas

of soil quality improvement (The Nature Conservancy, 2021). While Kula Bio is committed to helping farmers to enhance crop production and reduce environmental impact by providing sustainable N solutions through developing fungal biological N fertilizers that reduce runoff losses of N. Pattern Ag offers soil microbiota analysis, and based on that, makes recommendations for the management of farm inputs. Stony Creek Colors aims to improve market-based alternatives for growers to diversify crop rotations by promoting sustainable, plant-based dyes like indigo for the cosmetics, textile, and food markets. Swarm Farm's automated, robotic farm technologies enable the precise application of fertilizers, pesticides, herbicides, and other crop-protection chemicals. The collaborative efforts by the firms promote a regenerative and nature-positive production paradigm.

Case study: India

The Government of India (GoI) has taken many initiatives to check soil degradation and improve/maintain soil fertility status in the country through launching several plans/programs/schemes/projects. These programs encourage the agricultural community to adopt best practices in agricultural waste management and avoid crop residue burning (Fig. 7). For instance, the National Mission for Sustainable Agriculture (NMSA), Soil Health Card (SHC) Scheme, Soil Conservation in the Catchments of River Valley Project and Flood Prone River (RVP&FPR), Reclamation and Development of Alkali and Acid Soils (RADAS), Nutrient-based Subsidy (NBS), production of neem-coated urea, organic farming, Paramparagat Krishi Vikas Yojana (PKVY), National Action Plan for Climate Change (NAPCC), National Mission for a Green India (NMGI) under NAPCC, National Water Mission (NWM), National Mission on Oilseeds & Oil Palm (NMOOP), and Mission for Integrated Development of Horticulture (MIDH) (NAAS, 2018; Chaudhari, 2018) are involved in soil health management, directly or indirectly. The NMSA was launched in April 2014 to restore and reclaim problematic soils (Chaudhari, 2018). The GoI is promoting NMSA for agricultural sustainability in India, followed by the Soil Health Management (SHM) sub-scheme under the NMSA with the prime goal of establishing soil testing laboratories, biofertilizers, and vermicomposting units coupled with training and demonstration to farmers to promote fertilizer application based on plant demands (NAAS, 2018). To support this program, the National Mission on Soil Health Card began in 2015, which provides farmers with information regarding the nutrient status of soil through testing and appropriate fertilizer recommendations (Chaudhari, 2018). The MIDH, Rashtriya Krishi Vikas Yojana (RKVY), and the National Programme on Organic Production (NPOP) promote organic farming for enhancing soil quality. While RADAS promotes the development of land resources through Macro Management of Agriculture schemes. The NBS policy has been in force since April 2010, under which a fixed rate of subsidy is given for different macro- and micro-nutrients every year. Furthermore, urea, which is the most widely used fertilizer, is available to farmers only in the neem-coated form, which led to a 10% decrease in its consumption and improved crop yield by 6–17% (NAAS, 2018). It helped to reduce its use, nitrate leaching, greenhouse gas (GHG) emissions and improved crop yields.

The GoI started to pay attention to this concern and enforced Section 144 of the Civil Procedure Code (CPC) to ban the burning of paddy stover. The National Green Tribunal (NGT), a government enterprise, established under the National Green Tribunal Act, aims to restrain crop burning through recycling initiatives and increasing public awareness.

In addition to the government's strict action on residue burning, the GoI implemented the National Biogas and Manure Management Program (NBMMP) under the "Waste to Energy Mission" to establish biogas plants to use surplus residues effectively and prevent pollution (Shukla, 2007). Under this program, about 5 million families have installed biogas plants. The use of surplus residues in bio-composting is also being promoted under RKVY, i.e., a state Plan Scheme launched in 2007 with Central Assistance;

Fig. 7 Laws and programs for waste management.

farmers are trained in agro-waste bio-conversion and bio-compost production through demonstrations and training. National Policy for the Management of Crop Residue (NPMCR) initiated in 2014 by the Ministry of Agriculture & Farmers' Welfare (MoA&FW) promotes technologies for in-situ management and monitor of the monitoring of crop residues (Datta and Meena, 2021). In support of this, the Department of Agriculture Cooperation & Farmer's Welfare (DAC&FW) was launched under the scheme "Sub-Mission on Agriculture Mechanization for Crop Residue Management" in April 2014 to boost farm mechanization. The mission aims to demonstrate CRM machinery in farmers' fields at a rate of ~US\$ 55 ha⁻¹. The scheme mainly comprises three components, (i) Establish Farm Machinery Banks for Custom Hiring of in-situ CRM machinery, (ii) Financial Assistance to farmers for the Procurement of Agriculture Machinery and Equipment for in-situ CEM, and (iii) Information, Education and Communication for awareness on in-situ CRM. Mass awareness campaigns through radio and television programs, advertisements in print and electronic media documentation, demonstration camps, capacity-building programs, star campaigning, awards at the village level, etc. are being implemented across the nation. As a result of these collective efforts, residue burning events have been reduced by 30% compared to the base year of 2016 (MoA and FW, 2021). To stop residue burning and associated nutrient burning in soil, national guidelines have also been issued (NAAS, 2018).

New policy initiative recommendations for soil quality protection in India

Over the last three decades, the GoI has made a significant investment in halting soil degradation and declining soil fertility (Chaudhari, 2018), and several development plans have already been undertaken. At the national level, soil quality management is difficult to achieve without robust collaboration and networks between public and private organizations and institutions. The use of information and communication technologies may improve the relevance and effectiveness of these programs. A strong hands-on training network would be a key component of successful soil quality management programs. Major government policies must be re-examined in the light of the country's shifting priorities and the full potential of large programs like the soil health mission. The following are some of the key policies that must be implemented to restore, improve, and preserve soil quality and ensure agricultural sustainability in the country (Fig. 8) (NAAS, 2018; Rotz et al., 2021):

Solid collaboration and networks are critical for the successful execution of soil quality management initiatives at the national level. With the introduction of new technologies, the following issues must be considered:

1. In the country, land-use policies need to be revised to prevent productive lands from being transferred to other uses so that farmers have options to select crops and cropping systems according to the availability of water and other resources, land capability, socio-economic conditions, and the prevailing market price of the product so that sudden fluctuations in the market price can be avoided.
2. An urgent need to review and strengthen technologies developed by State Agricultural Universities and ICAR institutions to combat wind and water erosion. It is critical to pay more attention to the Himalayan region where the loss of soil, water, and human and animal wealth is rapid and alarming.

Fig. 8 Policy initiative recommendations for soil quality protection in India.

3. The SHC scheme must have a robust monitoring mechanism through identifying and strengthening key laboratories to ensure the quality and authenticity of the soil test data to make the scheme worthwhile. The scheme should also include plant tissue testing together with soil testing by appointing trained staff to provide advisory services to farmers to ensure practical implementation of recommendations.
4. Biofertilizers, microbial consortia, crop rotation, and organic manures should be an integral part of sustainable nutrient management. Local administrators (e.g., agricultural supervisor, research officers) must ensure their promotion and adoption among the farmers at the micro-level. To promote efficient utilization of organic manures and crop-livestock production systems, training and fiscal incentives should be given to farmers for better manure management and preparation of nutrient-rich composting.
5. Coating of N-fertilizers with nitrification inhibitors needs to be promoted to improve nutrient use efficiency (NUE) and reduce nitrate leaching. For this, incentives may be provided to the fertilizer producers opting to manufacture value-added fertilizers. Farmers should also be incentivized to adopt these products rather than imposing rules and regulations on them.
6. Farmers are compensated for agroecological practices and enhancing SOM through a wide range of programs comprising intended stewardship with due support from the administration.
7. Introduction of a long-term low-risk pesticide and contamination management policy that includes research and development as well as rules, regulations, knowledge transfers, and monetary enticements to make global agriculture a spearhead in low-risk pest management.
8. The SOM stock could be enhanced by expanding farmer-to-farmer support programs by encouraging farmers to work together in a team.
9. Supporting farmers in bringing more areas under a sustainable agroforestry system through implementing programs in which farmers get financial help.
10. Restrictions on the removal of buffer zones, windbreaks, and naturalized areas unless and until other habitats or areas are created.
11. Provide concrete financial and extension assistance to enrich the soil with OM, specifically through the establishment of perennial forages.
12. A policy of cross-compliance that involves penalties for mining SOM from their field by adopting exhaustive farm practices and technologies.
13. Tracking and measurement of soil quality and SOM on all farms in every province.
14. Introducing and implementing policies and strategies for the reduction of soil contamination as for water contamination policies.
15. Increase funding support for non-industrial farms, and small-scale and community-based farming at the state and national levels.
16. Implement policy restrictions on land ownership based on factors such as income, access to capital, properties, farm holdings, and, interest in provisioning food.
17. Promotion of food provisioning, consumption, and soil quality as a part of the primary and secondary school curriculum.
18. New methods of nutrient management, such as fertigation, nano-urea fertilizers, etc. should be promoted.
19. Efficient recycling and safe disposal of agricultural wastes should be strictly followed by introducing the policy in governmental campaigns.
20. The use of solar and wind energy in agricultural operations should be promoted by subsidizing the required equipment/instruments.
21. The introduction of carbon credits or incentives to farmers practicing conservation agriculture to sequester carbon and reduce GHG emissions.

Need to be supported by targeted plans and policies for soil management:

Support for soil developmental activities to monitor and forecast change in soil;

Enhance awareness and education about soil-related issues through integrating such topics across the curriculum, i.e., biology, geography, geology, economics, etc.

Investment in the development, testing, and dissemination of sustainable soil management practices and technologies.

Introduce appropriate and effective regulation and incentives, for instance, removal of subsidies on harmful practices including excessive use of synthetic fertilizer and pesticides. Subsidies could also be given to farmers to encourage the purchase of tools, machinery, and other inputs that are not harmful to soils.

Enhance capacity to manage soil resources sustainably to achieve regional, national, and international food security.

Conclusion

A sustainable soil ecosystem is needed to promote the global economy of the farming community. Key policy initiatives in terms of soil quality protection, maintenance of soil fertility, management, and recycling of agro-residues are vital components for the successful implementation of various scientific approaches toward sustainable soil quality. This chapter helps to promote policies,

plans, and strategies to enhance soil quality by including them as part of land-use planning. A variety of sectors must contribute to this planning to meet common goals such as food supply, water supply, and conservation of biodiversity. Therefore, governments should encourage and incentivize farmers to adopt eco-friendly land management technologies and other ecosystem services. Various eco-friendly practices and technological interventions can help with soil quality protection and boost agricultural productivity. Likewise, the formation of small and medium-sized agribusinesses engaged in sustainable land management should also be facilitated with financial support by the government.

Abstract

Owing to the scarcity of green spaces in cities, the installation of green infrastructure on façades and roofs have gained importance in providing a range of ecosystem services. Compared with natural soils, common growing media for green roofs and vertical green systems on façades consist of predetermined mixtures of organic and inorganic, natural, modified and synthetic materials, arranged in a soil-like horizon structure to provide anchorage, store and provide nutrients and water but allow fast drainage. They are referred to as Technosols, soils having large amounts of manufactured and modified materials (artifacts), and can be adapted for each greenery system.

Key points

- Green roofs and vertical green systems are engineered environmental design features installed for economic, environmental, or ecological reasons.
- Green roofs and vertical green systems must have appropriate growth media to sustain vegetation in harsh environmental conditions, such as strong winds, long periods of direct sunlight, drought, or strong rainfall.
- Growth media of green roofs and vertical green systems can be classified as Technosols and consist of deliberate mixtures of organic and inorganic, natural, processed and/or recycled materials, arranged in a soil-like horizon structure.
- Preferred and commonly used materials in the mixtures are coarse, lightweight and porous to retain water and simultaneously allow a fast drainage, while avoiding high weight loads on the structures.
- Green roofs and vertical green systems mitigate the urban heat island effect, reduce energy consumption for cooling buildings, reduce air pollution, create habitats for biodiversity, and regulate flooding through the runoff reduction.

Introduction

Since the beginning of civilization urban areas have been cultural hotspots, centralizing government activities, health care, transportation, industrial and commercial activity. They thus play an important role for humans. But urbanization always implies drastic human-made modification of the local environment along with a huge consumption of resources and disposal of the residues.

The world population of humans is continually increasing, being expected to reach more than 9 billion by 2050 with an increasing proportion living in urban areas. As a consequence, cities are continually expanding. In 2009, urban areas covered 3.5 million km² (i.e., 2.6% of the total land areas excluding Antarctica and Greenland), in which 0.6% of soils are covered by impervious surface (Liu et al., 2014).

Urbanization impacts negatively on the environment by disrupting water and nutrient cycles and emitting pollutants. The land use change, and especially surface sealing with concrete or asphalt for roads and housing is one of the main drivers of such disruption: it implies biodiversity loss, decreased groundwater recharge, water uptake and evaporation by the vegetation, and raised surface runoff. Thus, the urban surfaces heat rapidly causing the urban heat island effect (Scalenghe and Marsan, 2009).

A conjunction of strategies to mitigate the negative impacts of urbanization and increase the resilience of urban areas consists of the conservation and refurbishment of existing vegetated areas, as well as the generation of new green infrastructure. Green infrastructure (GI) is defined as natural, semi-natural areas, and engineered environmental design features that are strategically interconnected also with other natural areas and provide multi-ecological functions (Maes et al., 2015). Crucial ecological functions provided by GI are the improvement of air and water quality, reduction of water runoff into sewer systems, filtering of noise, microclimate stabilization, food production, improvement of psychological and physiological human health, and strengthening social relationships by attracting people to outdoor spaces (Ampim et al., 2010; Haaland and van den Bosch, 2015; Mentens et al., 2006; Jaffal et al., 2012). Economic advantages include increased tourist activities, reduced energy use for indoor temperature regulation, lower wastewater treatment costs, and increased property value, which generates more tax revenue (Tzoulas et al., 2007; Abass et al., 2020).

GI ranges from completely human-made constructions (e.g., green roofs) to natural ecosystems. Some examples of GI are:

- public and private parks and gardens
- tree pits
- orchards, urban agricultural and horticultural lots
- green façades
- extensive, intensive and semi-intensive green roofs
- infrastructure for rainwater harvesting such as bioswales, infiltration basins and trenches, filter strips, and ponds

Despite their desirability, the installation of new large green areas in densely populated cities entails many challenges. The number of available areas is limited, many of them have inappropriate soil quality to sustain vegetation. Also, the installation of green areas competes for priority with land designated for residential, commercial, or other service uses. Constructing a new green area requires a large amount of financial, human and natural resources. In particular, high quantity natural soil material from periurban areas has to be introduced to offset the poor quality of urban soils. Moreover, municipal administrations hesitate to implement green infrastructure projects due to the difficulty of evaluating their economic benefits (Haaland and van den Bosch, 2015).

In this chapter we focus on the green infrastructures of green roofs and vertical green systems, as they are versatile design features compatible with residential and commercial land use, thus reducing conflicts of interest and providing ecological and social benefits associated with vegetated areas. We present an overview of the technical aspects of green roofs and vertical green systems and how their installation design and the local conditions constrain the criteria for establishing the growing media and the plant selection. In particular, the pedogenic characteristics of the growing media and the commonly and alternative materials used are addressed.

Green roofs and vertical green systems

Due to the scarcity of available areas, the use of alternative available spaces that were not necessarily intended to be vegetated (secondary urban greening; Flores-Ramírez et al., 2018) have gained importance, such as façades and roofs. Green roofs (GR) and vertical green systems (VGS) have the potential to provide a wide range of ecosystem services. The installation can be intentionally designed from the beginning of a projected building or can be adapted to cover existing structures by retrofitting. The selection of the vegetation can have esthetic (greenery), protective (against wind erosion and storm water impacts), or productive (agriculture) purposes. Importantly, their creation requires almost no horizontal space on the ground, and are thus a versatile and promising option for growing cities.

Together with green balconies, GR and VGS conform what is called greenery systems, and are considered part of the architectural style of buildings (Fig. 1). In recent decades, greenery systems have spread widely as architectural and constructive elements in the design of façades and roofs (Abass et al., 2020). A commercial boom with new substrates, structures, and plant selection has thrived in many countries of the global north, where regulations for their installation have been established (e.g. the German Regulation for GR "Dachbegrünungsrichtlinien" FLL, 2018). But they are also spreading to other latitudes (Asia, Latin America). However, the esthetic and technical aspects have been prioritized over the environmental ones (Besir and Cuce, 2018).

Fig. 1 From left to right: Examples of an extensive green roof (first two left images) a semi-intensive green roof (third image), a green façade (fourth image) and a modular living wall (right). Photos Eleonora Flores, Stefan Abel and Geoffroy Séré.

Technical aspects of green roofs

Green roofs (eco-roofs, roof gardens, living roofs) can be defined as roofs coated with a layer of growing medium, which supports vegetation (Abass et al., 2020). Depending on the depth of the growing medium and the technical and biotic possibilities and challenges, the GR are classified into three groups: extensive, semi-intensive, and intensive (Table 1). The extensive GR implies a light construction design, it is shallow and easy to maintain as the commonly used vegetation with shallow root systems is quite stress resistant within local climate conditions. The selected plants should endure long dry periods without irrigation (e.g., species from the family Crasulaceae, and the *Sedum* genus in particular) or be adapted to areas with frequent precipitation (e.g., combinations with moss and lichens). The semi-intensive and intensive systems have more volume for root growth and commonly include an irrigation system. These systems can support a wider selection of plants, ranging from herbs, woody bushes and even small trees (<10 m), but deeper substrates also require more maintenance. For all types of GR but particularly for extensive GR systems, it is highly recommended that native plant species are selected, as they are well-adapted to local climatic conditions. The hours of intensive solar radiation as well as shading have also to be considered in vegetation selection and the inclination angle of the GR to be installed.

In general, despite all the current variations and commercial possibilities that the market offers, the basic structure of GR from top to bottom (Fig. 2), apart from the vegetation and the substrate, consists of:

- Filter sheet: made of a polymer non-woven fabric, e.g., fleece, which avoids finer particles of the substrate being transported downwards with the infiltrating water or the penetration of roots, both of which can clog the drainage system.

Table 1 GR characteristics.

Characteristic	Extensive GR	Semi-intensive GR	Intensive GR
Structural requirements	Suitable for retrofitting buildings, sloped roofs, large sized areas	Suitable for retrofitting buildings, medium sized areas	Requires planning in advance of construction of whole building Not suitable for sloped roofs
Thickness of substrate layer	Low weight load capacity 6–20 cm	Moderate weight load capacity 10–25 cm	High weight load capacity >25 cm
Particle size distribution of drainage layer (when made of aggregates)	2–8 mm to 2–12 mm	4–8 mm to 2–16 mm	4–8 mm to 16–32 mm
Weight (under water saturated conditions)	50–150 kg m ⁻²	120–350 kg m ⁻²	> 300 kg m ⁻²
Common vegetation	Small: succulents (suitable for arid and semi-arid zones), grasses, mosses (in humid climates)	Medium size: Shrubs, grasses, seasonal herbaceous plants	Large size: from grasses, succulents, shrubs, and small trees.
Irrigation	Seldom. In case of extreme drought only	Periodically/Seasonally	Regularly
Roof slope [%] and inclination [°]	Up to 100% (45.0°)	< 20% (< 11.3°)	< 5% (2.9°)
Costs	Low - medium	Medium	High
Construction and maintenance investment	Low	Medium	High

Modified from González-Méndez B and Chávez-García E (2020) Re-thinking the Technosol design for greenery systems: Challenges for the provision of ecosystem services in semiarid and arid cities. *Journal of Arid Environments* 179: 104191.

Fig. 2 Schematic profile of a simple extensive GR.

- Drainage layer: either made of mineral materials with large grain sizes that allow the water to percolate rapidly (such as gravel, expanded clay or pozzolana) or geosynthetic drainage layers with a special core system. This layer is necessary to reduce the risk of water stagnating in the root zone.
- Root barrier: often a geomembrane that prevents root penetration and consequent damage of lower waterproofing layer or the building structure. It can also be a sealed concrete or asphalt layer or consist of metal trays, which act as a waterproofing sheet. A properly installed geomembrane with welded junctions can work as root barrier and waterproofing sheet simultaneously.

Some variations include a single-layer construction, consisting of a vegetation supporting layer with drainage and filtering functions.

In a multilayer construction it is common to install an insulation layer between the root-barrier geomembrane and the waterproofing layer or the building structure.

The installation of an irrigation system on semi-intensive and intensive GR helps to sustain the vegetation, especially in areas with hot and dry climate conditions during the vegetation period.

Further technical considerations:

- I. The weight load capacity to install a GR must bear the total weight of substrate under water-saturated conditions, further installed facilities, plus the biomass weight. The structures and the substrates should therefore preferably be light.
- II. Low flammability: resistance against flying sparks and radiating heat. A maximum of 20% (*w/w*) organic matter (OM) is therefore recommended (FLL, 2018).
- III. It is desirable that the GR substrates have light hues, or high albedo, therefore reducing the adsorption of solar radiation and the consequent heating.

Technical aspects of vertical green systems

Vertical green systems (also called vertical gardens, green walls, vertical greens, vertical landscaping and bio-walls) are a diverse arrangement of installation designed to create a vegetation envelope on vertical building walls.

VGS consists of two systems relying on the facility for the plant root system and whether implemented outdoors or indoors (Fig. 3):

- a) green façades: the root system grows directly in the soil or in substrate-filled containers and the aerial part of the plants cover the building envelope. The vegetation cover develops directly on the wall (either with adventitious roots or adhesive pads) or on supporting structures attached on the wall but leaving a gap in between. Different performances in terms of temperature regulation will depend on this characteristic (Fig. 4A–C).
- b) living walls or green walls: the root system of the plants grows in large or small modules, panels, bags or similar structures attached to a supporting structure along the wall. Living walls therefore require more maintenance and a more elaborate infrastructure to place the growing substrates and the irrigation system than green façades (Fig. 4D). However, they allow a variety of plants to contribute to the uniform covering of the wall simultaneously, with modules that can be replaced easily if needed. This kind of VGS is preferred for indoor spaces. Among the diverse forms of living wall, the continuous system has no

Fig. 3 Differences between vertical green systems. Modified from Manso M and Castro-Gomes J (2015) Green wall systems: A review of their characteristics. *Renewable and Sustainable Energy Reviews* 41: 863–871.

Fig. 4 Examples of vertical greenery: (A) direct green facade, (B) indirect green facade with supporting structures for continuous guides, (C) direct green facade with supporting structures for continuous guides, (D) modular living wall with flexible bags.

substrate. It has a hydroponic system with lightweight absorbent screens where the plants are inserted and are continuously irrigated with a nutrient solution. The modular living walls do have lightweight substrates where the plants can easily root (Besir and Cuce, 2018; Manso and Castro-Gomes, 2015).

Constructed Technosols for green roofs and vertical green systems

The GR and VGS are totally human-made. Their construction challenge is to provide proper growth conditions for vegetation on surfaces that typically are not planned for that. Therefore, apart from the formal structural and architectural conditions, a proper growth medium and appropriate plant selection is crucial.

Unlike natural soils which develop in-situ over time, common growing media for GR and VGS consist of deliberate mixtures of organic and inorganic, natural, modified and synthetic materials, arranged in a soil-like horizon structure to provide anchorage for roots, store plant available water, drain water excess, as well as retain and provide nutrients for plants (Ampim et al., 2010; Rokia et al., 2014; Damas and Coulon, 2016). The growing media lies on an impervious layer, either concrete, a geomembrane or it is retained in a pot-like container.

In the World Reference Base of Soil Resources (WRB) such artificially constructed soils are classified as Technosols (IUSS Working Group WRB, 2022). They notably contain large amounts of artifacts (solid or liquid substances that are created or substantially modified by humans) ranging from ca. 20% (v/v) to a complete anthropogenic composition. They can be created circumstantially or with specific functional purposes, as in this case, to fulfill plant-supporting functions (Rokia et al., 2014; Damas and Coulon, 2016; Flores-Ramírez et al., 2018) for a diversity of GI substrates.

These Technosols can be mainly described as isolatic (from the Italian *isola*, island) due to the implementation design with soil depth of ≤ 100 cm separated from the native soil surface by an impervious layer (IUSS Working Group WRB, 2022). The supplementary qualifiers can be 'folic' for the installed organic layer, not constantly water saturated and well aerated, 'drainic' for systems with an artificial drainage, and 'transportic' with substrates formed from allochthonous natural soil by transportation, which can be used to elaborately describe the Technosols of GR and VGS. Further qualifiers depend on the technical origin and characteristics of parent materials.

Commonly, the GR and VGS growing media is a mixture of extracted and relocated materials from natural origin (e.g., sand, peat, light volcanic rocks as pumice and scoria) and diverse commercial and recycled materials (e.g. expanded clay, compost, bricks, tiles, debris). The construction of Technosols as plant growing media implies the intentional optimization of the physical, chemical and biological characteristics of the mixtures adapted to the local climate conditions inside the boundaries of the infrastructure requirements the GR and VGS. Therefore, there is no all-purpose growing medium, however, it has to meet the general physical and chemical requirements discussed next.

Physical requirements of GR and VGS Technosols

Main physical characteristics to be considered for GR and VGS substrates are: large water holding capacity, large hydraulic conductivity to avoid waterlogging and facilitate drainage, small bulk density, sufficient air filled and total porosity.

Water holding capacity and drainage

An adequate growing media should be able, simultaneously, to balance the fast drainage needs with the capacity to store water that is available to plants, i.e., hydraulic conductivity and water holding capacity.

The capacity of a growing media to store, as well as to drain water, depends on its pore system. The available water capacity (AWC) is the water retained against gravity by the pores ranging from 0.2 to 50 μm . Smaller pores retain water that the roots cannot extract, and larger pores drain the water faster than the root can take it up.

In natural soils a well-balanced mixture of organic matter (OM), clay and silt provide an appropriate matrix for water retention. However, fixed weight and load capacities of the supporting structures limits the weight of GR and VGS (except green façades), thus, in general the amount of natural topsoil (with a large particle density and heavy when saturated with water) must be reduced and replaced with lighter materials able to store water. Also, the content of finest particles, particularly clay, must be reduced as they could migrate downwards, and clog the drainage systems. Some guidelines recommend reducing the silt and clay particles with sizes ≤ 0.063 mm at $\leq 20\%$ (v/v) for intensive GR and $\leq 15\%$ (v/v) for extensive GR. This has led to a general use of growing media, which includes a large content of porous materials and up to 20% (w/w) of OM (González-Méndez and Chávez-García, 2020). Examples of light porous materials are expanded clay, expanded shale, scoria, and perlite.

Commonly, the intraporous structure within the porous material retains water while allowing the drainage of water excess through the larger intra- and interparticle pores (Fig. 5). They have a low bulk density and large grain sizes, which provide good aeration and reduce the clogging of the drainage systems. The AWC depends further on the connectivity of the intra- and interparticle systems. A disruption in capillary continuity can hinder water exchange and thus reduce AWC (e.g., the ceramic cover of expanded clay). Also, some porous materials partly exhibit closed pores which are not accessible and do not contribute to AWC, e.g., some scoria (Flores-Ramírez et al., 2018). Their performance can be improved by crushing.

Fig. 5 Schematic representation of (A) intrapore system within porous materials, (B) interparticle pores among porous and solid particles, and (C) porous materials which partly exhibit closed pores.

Fig. 6 General physical characteristics of the substrates in the GI where the substrate depth allows a multilayer system. Particle sizes, hydraulic conductivity and air capacity increase from top to the bottom, and the water retention concentrates in the rooting zone.

As previously mentioned, having a drainage layer at the bottom of the structure is crucial for all GR and VGS to avoid waterlogging and plant 'drowning' after large rainfall events. In addition, a high hydrostatic potential may also harm the waterproofing layer and may lead to water leaking.

A multilayer system (Fig. 6), each with various functional substrate layers and with particle sizes increasing from the top to the bottom, can maximize the AWC without decreasing adversely the hydraulic conductivity of the overall installation. Thus, a balanced relationship with water storage at the top, capillary rise at the intermediate layers and drainage at the bottom is recommended.

Organic matter beneath the growth substrate has to be avoided, as it decomposes, forming a biofilm that can clog the drainage, affecting plant growth, and increasing the weight of the GR (Ampim et al., 2010).

Extensive GR and modular systems of living walls

As this design has the shallowest substrate layer and root zone, and lacks an irrigation system, the AWC of the growth substrate is most crucial for plant growth and has to be maximized. An AWC of at least 15% (v/v) should be achieved. However, due to limits in weight load capacity the use of common substrates of a multilayer system is restricted and mostly coarse grained and porous substrates are used, which exhibit reduced AWC (Fig. 7). For drainage, a hydraulic conductivity of $0.6\text{--}70\text{ mm min}^{-1}$ is recommended for a multilayered GR construction and $60\text{--}400\text{ mm min}^{-1}$ for a monolayered construction (FLL, 2018). In arid or very humid regions the requirements may be even higher.

Semi-intensive and intensive GR

These GI are more similar to a conventional terrestrial garden; the AWC may not be the main concern as they have a deeper rooting area and commonly an irrigation system, which can nevertheless be optimized through the use of a proper substrate. For such systems the weight of the substrates used is often the crucial factor and light substrates are preferred. For drainage, a hydraulic conductivity of $0.3\text{--}30\text{ mm min}^{-1}$ for a multilayered GR construction and $60\text{--}400\text{ mm min}^{-1}$ for a monolayered construction is recommended (FLL, 2018). In arid or very humid regions the overall requirements for the substrate may be even higher.

Green façades

This kind of GI have a special challenge, because they have a relatively small volume for rooting and water supply, given the large aerial biomass they sustain. This implies a maximized leaf area for transpiration (and plant species-specific transpiration rates). It thus translates into greater watering needs.

For a central Europe climate (Berlin), Hoelscher et al. (2016) found an average daily transpiration rate (measured with daily sap flow rates) of $0.7\text{ L d}^{-1}\text{ m}^{-2}$ of covered wall area and a variation in the maximum daily transpiration rates (hot summer days) of the three plants studied from 1.3 to up to $2.3\text{ L d}^{-1}\text{ m}^{-2}$ of covered wall area: *Parthenocissus tricuspidata* (adhesive pads) < *Hedera helix* (adventitious roots) < *Fallopia baldschuanica* (needs climbing aids), which can roughly be translated into irrigation needs. For example, a leaf area of 36 m^2 of *P. tricuspidata* would need between 18 L d^{-1} to up to 46.8 L d^{-1} in summer. This illustrates the importance of irrigation or a sufficient AWC of the substrates.

Fig. 7 General physical characteristics of the substrates in the three types of GR, from the shallow substrate layer of the extensive GR to the thicker substrate layers of semi-intensive and intensive GR.

Particle structure, bulk density (ρ_b), and air capacity

The constructed Technosol must have sufficient structural stability to avoid wind removal of the substrate, compaction, and to provide overall stability for the plant-substrate system against mechanical stress due to wind. This is mainly determined by the particle size distribution and the particle shape. Coarse crushed angular solid or porous particles provide a better interlinking of the substrate lattice and are recommended as structure-forming materials for extensive GR. For extensive GR a poorly-graded particle size distribution is recommended to minimize weight load, whereas well-graded particle size distribution is recommended for intensive GR and VGS.

Nevertheless, when the weight load capacity enables large loads, an installation of well-graded substrates on extensive GR maximizes the AWC.

When substrates with poorly-graded particle size distribution are used, the filter-stability of the substrate itself is critical leading to suffusion of the small particles and therefore a filter fleece should be applied to avoid clogging.

The largest particle size recommended are:

- For layers up to 10 cm: 12.5 mm
- For layers >10 cm: 16 mm

and a maximum content of 15–20% (v/v) for particles <0.063 mm (FLL, 2018).

The bulk density (ρ_b) of the substrate installed on supporting structures must be small to avoid exceeding the structural weight load capacities. Furthermore, the ρ_b corresponds with the root penetration resistance, thus a small ρ_b enables proper root growth. A dense root network is crucial for structural stability of the system, increasing the resistance against wind removal of the substrate as well as windthrow.

According to FLL (2018), appropriate bulk densities range from 0.6 to 1.2 g cm⁻³ or 1.0 to 1.8 g cm⁻³ at field capacity for all GR types. To achieve such a ρ_b unintended compaction during installation has to be avoided.

Substrates should have an air capacity of at least 20% (v/v) to guarantee adequate drainage (Ampim et al., 2010; FLL, 2018). At an air capacity less than 5% (v/v), which implies simultaneous high level of compaction, poor aeration as well as impedance of root growth occurs. Some researchers claim that an optimal distribution in terms of solid, water, and air phases should be 40, 40, and 20% (v/v), respectively (Ampim et al., 2010).

Chemical requirements of GR and VGS Technosols

Important chemical properties include pH, buffering capacity, cation exchange capacity (CEC) and chemical stability, which determine the nutrient availability and the leachate quality. It is important to consider that one of the problems presented by the use of chemical properties as indicators of Technosol quality is its high seasonal variability and Technosol management (e.g., nutrient supply, irrigation, climate.).

pH

The commonly accepted range of pH for optimal plant growth ranges between 5.5 and 8.5 (FLL, 2018), as plant nutrients are usually most available between pH 5.5 and 7.0. However, it will depend on the plant preferences (e.g., wetland plants prefer acid pH) and also on the environmental conditions, such as acid rain, which needs to be buffered by alkaline substrate to counteract the acidification.

Buffer capacity

The soil buffering is governed by the protonation and deprotonation of minerals (e.g., aluminosilicates or CaCO₃) and organic matter, which act as sinks for H⁺ and OH⁻ ions to maintain a relatively stable pH despite acidifying or alkalizing factors. It maintains appropriate pH conditions for a wide range of plants and microorganisms. The composition of the constructed Technosols determines the buffer capacity depending on its minerals. The application of fertilizers or other soil conditioners can alter the buffer capacity (Huot et al., 2015).

Cation exchange capacity

The components able to absorb and desorb plant nutrients (e.g., Ca, Mg and K) in GR and VGS substrates are mainly the OM and some clays of colloidal size (< 1 µm), which have a surface charge and thus provide a high CEC. However, common inorganic substrates lack clay and most of their components have a low or neglectable CEC (e.g., perlite, sand etc.). In these cases, plants growing on these substrates may need additional nutrient supplies (Ampim et al., 2010). Nutrient leaching has to be avoided adjusting fertilizer application to the nutrient demand of plants.

Chemical stability

Weathering of inorganic components and degradation of organic components might, over time, modify the CEC and pH of a Technosol depending on the rate of both processes, just as in natural soils. Consequently, the C:N of the organic matter and climatic factors, such as precipitation and temperature, determine the mineralization rate and thus the release of nutrients for

microorganisms and plant uptake. The chemical stability can be a decisive factor for the long-term stability of a Technosol (Séré et al., 2010; Huot et al., 2015).

Biological activity

The biological activity refers to the organisms living in soils and their interaction with the soil matrix. As in natural soils, organic substrates as well as dead tissues of the plants growing on the GI are transformed by organisms colonizing the constructed Technosols, especially bacteria, algae, protozoa and fungi but also nematodes and plants. This transformation occurs through changes in pH driven by acids released by plants and bacteria, the processes of mineralization (conversion of organic components into soluble mineral compounds) and humification (decomposition of fresh organic matter, which results in stable organic substances). Mineralization products are much simpler molecules (e.g., NH_4 , NO_3^- , PO_4^{3-}) that can be absorbed by plants. Humic substances can form strong bonds with clay minerals and oxides (organomineral associations). Pedoturbation lead by nematode activity modify the Technosol matrix by making bores and burying materials at greater depth. This can lead to the formation and stabilization of aggregates and modify the distribution and sizes of the pores, implying a change in the water retention and aeration capacities (Huot et al., 2015).

The biological activity as a sensitive parameter for organic residues transformation is very dynamic and a quality criterion for the soil fertility and aggregate stability. Indicators of the biological activity include microfauna and mesofauna biomass, soil respiration, metabolic quotient ($q\text{CO}_2$), and diverse enzymatic activities. Microbial biomass and activity correlate with carbon and nitrogen contents of the soil, potentially mineralizable nitrogen, soil respiration and enzymatic activity. Soil respiration is most widely used as an indicator of microbial activity and decomposition rate of organic substrates. Estimation of the enzymes involved in the C, N and P cycles allows the calculation of the functional diversity of the microbial communities. The microbial biomass expresses the number of organisms, mainly fungi, bacteria, and protozoon that have a relationship with the flow of energy and nutrient transfers.

Biological and biochemical properties respond quickly to changes in soil management and are sensitive to environmental stress.

In constructed Technosols the biological activity depends on the physical and chemical properties of the substrate's parent material, affecting water retention, water flow and nutrient supply. In GR and VGS a large number of substrates lack well established microbial communities, as most of their components have been sterilized through their thermal production process (commercial materials, e.g., expanded clay) or exhibit poor colonization (e.g., natural perlite, recycled construction debris; Huot et al., 2015; González-Méndez and Chávez-García, 2020). Therefore, to improve plant support capability, deliberate addition of OM, for example with an already active microbial community, microbial inoculums or earthworms, is recommended (John et al., 2017; Jusselme et al., 2019). Autonomous colonization of the substrates by micro and mesofauna is also possible, but it is a slow process.

Parent materials and constructed Technosol composition

A constructed Technosol for GR and VGS must address mainly the suitability for the kind of GI, the target vegetation, the climatic conditions, as well as the availability and cost of the components. There are already a large number of commercial mixtures available in the market that may meet these requirements. However, a non-commercial environmentally-focused Technosol design can address a number of crucial social and environmental issues by prioritizing the use of locally-sourced materials and the incorporation of locally-available wastes. This will limit the negative impacts of natural soil extraction and transportation, and help to close the global nutrient cycle, which is disrupted by the urbanization processes; in addition, it reduces the installation costs.

Among the common components (commercial and non-commercial) used for Technosol construction are natural soils, as well as artifacts (both may provide OM input). Among the artifacts are technogenic materials, particular recycled materials and wastes, as well as semi-natural materials including excavated soil materials (from C horizons) and sediments. These materials are described in more detail in the following paragraphs.

Natural soils and natural mineral materials

The inclusion of natural soil for extensive GR is not frequent, owing to its disadvantages related to weight and drainage clogging, but is used in other GR and VGS. Preferred natural soils are sandy-loam, turfy-soil, sandy-silt, and sandy soils (González-Méndez and Chávez-García, 2020). The advantages of including natural topsoils rely on their content of micro and macro biota, OM and nutrients. The main disadvantage is the environmental impact of the extraction and transportation of large quantities of topsoil from surrounding agricultural or forest areas to vegetate others. For example, in the surroundings of Mexico City, between 45 and $532 \times 10^3 \text{ Mg a}^{-1}$ of organic forest soil (locally called *tierra de monte*) were extracted from 1997 to 2014 (Abbruzzini et al., 2022) and in France, $3 \times 10^6 \text{ m}^3$ of topsoil are used each year (Rokia et al., 2014) to produce ornamental plants and the installation of other GI.

In contrast to natural soils, natural mineral materials obtained in mines can be purchased with defined characteristics and later mixed and optimized according to purpose. Commonly used natural mineral materials for GR and VGS are sand, gravel, clay, and volcanic rocks. Among the later, particularly lava (scoria), pumice, perlite, or any pozzolan material are widely used (Fig. 8A and B). Sand and gravel provide good drainage, but exhibit a large ρ_b when installed. Clay provides in general good nutrient retention, but may clog the drainage. Therefore, clay should be used in small amounts, and sand and gravel preferably in VGS on ground. The

Fig. 8 (A) Lava (scoria), and (B) pumice as examples of porous natural mineral materials. Thermally expanded clay (C) and (D) thermally expanded slate as examples of porous processed natural materials.

porous volcanic rocks commonly increase the AWC of the constructed Technosols. Although some may have closed, occluded, or dead-end pores not available for water storage, like some pumices (Flores-Ramírez et al., 2018), they can be an ingredient of a mixture to improve the drainage, aeration, and lightness of the mixture.

Processed natural materials

Clay, slate, perlite, vermiculite, and glass commonly have large porosity when thermally expanded (Fig. 8B and C). Although for some materials the AWC may be poor, they can be used for drainage and to reduce the mixtures weight (González-Méndez and Chávez-García, 2020). Their production implies a very high energy input as the natural minerals are heated to around 1200 °C, increasing their environmental footprint when produced.

Recycled mineral materials

Mineral wastes are the main part of overall accrued wastes worldwide. They include wastes from construction works, soil excavation and mining operations. Efforts to minimize solid waste disposal in landfills and to encourage recycling are increasingly common (Hendriks and Pietersen, 2000).

Using locally available wastes for the construction of Technosols is a viable strategy to diminish the demand of natural soil for the installation of GI (Abbruzzini et al., 2022). Characteristics of urban wastes differ, and the possibilities and suitability of their use as components for constructed Technosols must be assessed previously.

From the huge diversity of wastes and by-products that can be found in urban areas only some of them are suitable for use as constructed Technosol components, such as construction and demolition waste (C&D) that constitutes around 35% of the total solid waste worldwide (Hendriks and Pietersen, 2000). To use C&D as substrate it needs generally to be processed and crushed. In many countries only the minor share of the overall waste is recycled (Gálvez-Martos et al., 2018), while in others the recycling of C&D is quite common (e.g., in Germany 59.7 t out of 73.9 Mt. of wastes were recycled in the overall construction industry; UBA, 2021). Thus, there is still a big potential in many countries to reuse C&D, such as in GI.

Main criteria to select waste materials for Technosol construction are the following (Damas and Coulon, 2016):

1. Non-toxic for human health or living organisms.
2. Easy to handle: granular solid materials should be preferred (no liquid and pasty wastes) and.

3. Appearance: the wastes have to generate minimal disturbances to the local population (i.e., organoleptic criteria such as smell or dust emission).

Countries may have legal requirements for the incorporation of recycled wastes in GI to be taken in account.

If the wastes fulfill those basic criteria, at least one additional criterion is required. Either they allow vegetation development, have geotechnical properties (such as stability, plasticity and cohesion), or both. Bricks may be a good example of both characteristics, as they are easily penetrated by roots to extract the water stored in their pores (Nehls et al., 2013).

Following the use of C&D and excavated soils, a constructed Technosol can be produced along with the installation of new buildings. Consequently, the general costs of the GI will be reduced and their inclusion in low-income neighborhoods may mitigate some environmental justice issues. Among the most used recycled mineral materials used as components of constructed Technosols for GR and VGS are crushed clay bricks, crushed roof tiles, crushed concrete, building rubble, and soils removed from construction sites.

Natural and recycled organic materials

Common materials providing OM to GR and VGS are compost, biochar, coconut coir, bark and processed sawdust. Compost is produced by the biological decomposition of organic wastes and acts as fertilizer. However, its quality depends on its maturity and the feedstock used. The usage of large volumes should be avoided due to high water retention and increase of the total load during rain events, as well as the possible contribution to eutrophication (Ampim et al., 2010; González-Méndez and Chávez-García, 2020).

Biochar is produced by pyrolyzation of biomass. Biochars generally have high C-content, porosity and CEC. These properties are suitable to increase overall substrate AWC, while decreasing its bulk density. However, their properties are highly variable and mainly depend on the production conditions and feedstock. Additionally, there can be negative effects due to the addition of pollutants (salts, PAHs, dioxins, furans, etc.) or due to nutrient immobilization (González-Méndez and Chávez-García, 2020).

Compressed or composted coconut coir, can be a suitable substrate due to its lightweight. Additionally, its water content when saturated can amount up to the quintuple of its own weight, which has to be considered in the load capacity of the infrastructures (Vijayaraghavan and Raja, 2014).

Sawdust is a low-cost and lightweight material, and may improve AWC, whereas bark may improve the air capacity. However, depending on the tree species, some of their components can be toxic to some seedlings, making a pretreatment such as composting necessary (Ampim et al., 2010).

Rubber crumb, made by grinding of e.g., disposed tires, may improve the properties of coarse-grained growing media by decreasing their bulk density and increasing the water retention (Zhao et al., 2009). However, this kind of material may contain PAH and may emit microplastics (Armada et al., 2022).

Soil amendments such as superabsorbent hydrogels, made out of polyacrylamide or modified cellulose, which are three-dimensional matrixes of highly hydrophilic crosslinked polymers, can be used to improve water retention (Chang et al., 2010).

Substrate composition – defining the optimal ratios

Many of the materials listed above, depending on their availability, costs, properties and durability could be selected to be mixed at different ratios. But how to know which mixture is adequate as a substrate? Guidance on the mixture ratios can be deduced from the bulk density and organic matter requirements established in the regulations indicated above.

The necessary and acceptable ratio of each mineral components of the mixed substrate has to be estimated regarding the weight load capacity (particularly for GR) and the ρ_b of the substrate. Thereby the individual ρ_b and total ρ_b of the mixture have to be considered. The more well-graded the mixture, the greater the expected ρ_b . The same applies to the AWC; however, to a certain point the air capacity decreases. Large proportions of fine particle should therefore be avoided. In a further attempt to optimize substrate mixtures, Willaredt et al. (2022) proposed determining mixing ratios by modeling and evaluating the water retention characteristics of the mixtures based on the water retention characteristics of individual components.

The addition of OM, such as compost, which contains relatively large amounts of nutrients, should be estimated by considering the nutrient demand of the vegetation. For other organic substrates, such as bark and peat, nutrient release occurs more slowly; the added proportion of these should therefore be determined by their effects on physical properties.

The proportion of OM should not exceed 20% (w/w).

Aging and early pedogenesis

As Technosols, GR and green facade substrates are susceptible media prone to early and fast pedogenesis (especially after their installation), which will lead to a change in their physical and chemical properties (Séré et al., 2010; Huot et al., 2015). The mixtures of each created substrate will act as parent materials, and they will determine the presence of specific pedogenetic processes under the influence of other soil-forming factors, such as climate and biota, similar to that in natural soils (Huot et al., 2015). Evidence for

these fast changes have been generally assessed through physical and hydraulic properties, although with contrasting results due to the heterogeneity of the Technosols.

For example, some studies have shown that water retention has increased relative to new substrates because of changes to grain size (e.g., increase of finer particles), number of micro-pores and macro-pores, and greater bulk density over time (Bouzouidja et al., 2018). However, other authors report the lack of influence of the age of GR and green façades on their hydraulic behavior (Mentens et al., 2006). Finally, evidences of an early pedogenesis were highlighted on GR substrates considering fine particles eluviation, organic matter mineralization and modification of soil matrix (Fig. 9; Bouzouidja et al., 2018).

The assembling of knowledge about pedogenesis in GR and VGS based on the relation between physicochemical properties and substrate performances over time is ongoing and has been accelerating for some time, with more information expected in the near future.

Benefits provided by GR and VGS in the urban landscape

The promotion of biodiversity and ecosystem services is an emerging major issue for the renewal of urban areas. GR and VGS contribute to some extent to the improvement in the environmental quality of urban areas, particularly of areas considered as 'dead spaces', which in the case of roofs represent 20–30% total surface after urbanization (Besir and Cuce, 2018). The provision of ecosystem services identified at the beginning of this chapter provided by the GR and VGS mainly result from their capacity to:

- regulate energy consumption and balances of buildings, through shading, evapotranspiration, and thermal insulation
- regulate water fluctuations in urban areas by increasing local water retention and evapotranspiration
- improve air quality
- improve local biodiversity

Energy consumption and energy balance of buildings

Diverse reductions in levels of energy demand of buildings have been reported for different climate conditions and GIs when compared with bare roofs or where walls were poorly insulated. The evapotranspiration rates and thermal properties of GR and VGS are strongly connected to the vegetation species used and to the substrate depth. These GI act as insulators decreasing external heat flow as the growing medium stores energy and the foliage provides shade and evaporates water (Jaffal et al., 2012; Hoelscher et al., 2016). In a mediterranean climate, Silva et al. (2016) monitored the evapotranspiration and assessed the energy balance in

Fig. 9 Evidences of an early pedogenesis on GR substrates considering fine particles eluviation and organic carbon mineralization after 4 years. S0 means original substrate. Adapted from Bouzouidja R, Rousseau G, Galzin V, Clavierie R, Lacroix D, and Séré G (2018) Green roof ageing or isolatic technosol's pedogenesis? *Journal of Soils and Sediments*, <https://doi.org/10.1007/s11368-016-1513-3>.

buildings having an extensive, a semi-intensive or an intensive GR. Buildings with any of the three GR had similar heating needs in winter, but those having semi-intensive and intensive GR needed less cooling energy (36% and 17% of the energy used in the building having an extensive GR, respectively). The three GR performed better than conventional roofs (white and black) in terms of annual energy use in the following order: conventional black roof > conventional white roof = extensive GR > semi-intensive GR > intensive GR (up to 70% less energy than conventional black roofs).

Hoelscher et al. (2016) showed that green façades have a cooling effect on the surface wall temperature, with differences up to 15.5 °C lower on vegetated walls than on bare walls, even performing better than bare white walls with high solar reflectance. The cooling effect is mainly provided by shading more than by plant transpiration.

Flood risk reduction

Green roofs contribute to the urban water management as their substrates store rainwater, thus reducing water runoff and flood risks (Mentens et al., 2006). Kolb (2004) mention a reduction of annual runoff by up to 70%. Moran et al. (2004) reported up to 85% reduction in peak flow rate. The frequency of precipitation and soil water content before rain event play a crucial role in the quantity of runoff delay (Bouzouidja et al., 2018).

Air quality

The macro- and micromorphological characteristics of the vegetation can increase the deposition surface to catch particulate matter, NO₂, and other pollutants improving thus the air quality (Tomson et al., 2021). Therefore, the installation of GR and VGS in adjacent buildings to the street canyons of highly transited roads is an appropriate strategy to improve air quality in urban areas.

Biodiversity

Numerous works show that GR and VGS can generate niches and supplementary habitat for a number of plant species, micro, *meso* and some macrofauna. A wider selection of (preferably native) plant species is recommended, with a further selection of plants that can provide forage and habitat for diverse biota, such as insects and birds (Williams et al., 2014). Also, these GI can be designed with a focus on creating specific microhabitats for target species, such as birds, by including a special topography of the substrate or small water ponds (Fernández Cañero and González Redondo, 2010).

Further increase of the biodiversity in GR and VGS is driven by colonization of new species over time, correlating positively with the proximity of larger patches of greenery and the mobility of the biota (Mayrand and Clergeau, 2018; Williams et al., 2014). However, some authors (Wang et al., 2022; Williams et al., 2014) emphasize that there is a lack of studies, which cover a larger number of taxa, including mollusk, fungi and arthropods, systematized methods to assess the biodiversity in GR and VGS, and a particularly poor understanding of effects on biodiversity in developing countries.

Furthermore, despite the fact that local benefits of individual GI have been confirmed, significantly larger areas covered by GI would be needed to improve the connectivity for species between green area fragments within a city, to act as stepping stones, implying a broad urban design and focused public policies (Mayrand and Clergeau, 2018; Williams et al., 2014). Nevertheless, GR and VGS can, to some extent, function as a mitigation tool for biodiversity loss from urbanization, even if their effectiveness is not comparable with natural habitats or ground-level urban complex artificial greening environments (Wang et al., 2022).

Conclusion

GR and VGS are purposely designed nature-based solutions. Installation of such green infrastructures has substantially increased within the past decade as awareness of stakeholders was raised by the need to reduce energy costs and the environmental impacts of construction design. The substitution of traditional roofs and building envelopes with GR and VGS can contribute to decrease the vulnerability of cities against impacts of climate change because of their contribution to mitigate the urban heat island, the reduction of energy consumption for cooling buildings, the creation of habitats for biodiversity, as well as the regulation of flooding through the runoff reduction.

Purposes for installation of GR and VGS are diverse and can rely on economic (e.g., reduced energy cost, additional esthetic value of real estate), environmental (e.g., regulating building thermal temperature and urban hydrological conditions) or ecological reasons (e.g., creating habitats, or pollutant removal).

The constructional requirements of targeted building determine the design of the installations and the Technosol selection. Substrate depth, its composition and plant species must therefore be appropriately selected to build a viable greenery in urban areas. The environmental footprint of its installation can be markedly reduced by using local and recycled material.

Substrates of GR and VGS require demanding physicochemical properties (e.g., small bulk density, large water retention, adequate nutrient provision) to create proper Technosols with a wide range of specific functionalities. The substrates properties and performances may evolve over time because of their early pedogenesis under the effect of such factors as climate and biodiversity. Such evolution has to be taken into account to assess their middle and long-term sustainability, although the studies of such processes are currently limited, but ongoing.

The GR and VGS can function as a mitigation tool for the biodiversity loss due to urbanization to some extent. A broad urban design and focused public policies aimed to increase the green infrastructure-covered areas would improve the connectivity for species between larger spots, to act as wildlife corridors, leveraging the overall functioning of the urban green infrastructures.

Abstract

This article synthesizes management considerations for environmentally sustainable stormwater control, maintenance, and construction of park areas, including golf courses and athletic fields. Recommendations cover landscape analysis, grading techniques, soil evaluation for plant selection, understanding soil types and water movement, and using the right tools and techniques to solve drainage issues. Examples include stormwater facility solutions using natural sustainable landscape design, as well as the construction principles and best infield mix for sports fields. Additionally, the article highlights challenges in managing vegetation along highways and rights-of-way. As synthetic fertilizers and pesticides are being phased out, park facilities and sports field managers must prioritize safety measures while maintaining acceptable playing surface quality and function.

Key points

- Management considerations for environmentally sustainable stormwater control, maintenance, and construction of park areas and sports fields.
- Recommendations include analyzing soil conditions, landscape surface grading techniques for water control in public areas and sports fields, evaluating soil conditions for plant selection, understanding how water moves through different types of soil, and applying the right tools and techniques to solve drainage issues.
- Examples of sustainable stormwater facility solutions, essential construction principles for the best infield mix for sports fields, and managing vegetation along highways and rights-of-way.
- Safety measures are important when reducing traditional inputs and maintaining acceptable playing surface quality on sports fields, golf courses, and public park thoroughfares.

*Retired USDA NRCS Soil Interpretation Leader.

Introduction

Soil management of public green spaces is a complex issue that involves creating functional and visually appealing environments while maintaining sustainable and non-toxic conditions. This is a balancing act for managers, who must consider soil type, quality, and conditions to determine stormwater management plans, plant selection, pesticide and herbicide use, and potential building sites.

Nature-based solutions have been recognized as more effective and cost-efficient than artificial alternatives. According to reports by ARUP, London, IUCN, and others in the World Economic Forums (2020, 2022, 2023), these solutions can be 50% more cost-effective on average and bring additional benefits such as improving resilience, boosting the health of citizens, and contributing to a safer and cleaner environment (Cavendish, 2022).

Managers must maintain a critical balance between aesthetics, function, and safety for the environment and human health. The public expects clean and green spaces that are free from toxicity and contribute to surface water pollution or human health safety concerns. Public entities that build and manage these properties are striving to show success in constructing and maintaining sustainable recreational facilities.

Many countries and local governments have developed regulations, ordinances, and guidelines for non-agricultural land management to protect environmental concerns, water quality, and human health. These regulations often require nutrient management plans or integrated pest management plans. Materials and engineering specifications for design and maintenance are also encouraged or regulated for physical human safety. ASTM International is an international standards organization that develops and publishes voluntary consensus technical standards for surface quality and safety design of school yards, playgrounds, sports fields, and golf courses.

To meet demands for safer alternatives, managers are rapidly developing and testing new techniques, such as using organic fertilizers and cutting back on pesticide and herbicide usage, to create well-kept athletic and leisure spaces. This is a challenging task, but with the help of professionals in various fields, it can be achieved.

Statement of problems

Prior to beginning sustainable maintenance planning for all public spaces, such as a park, sports field, golf course, or highway structure, environmental concerns have to be taken into account during the construction phase. The planning process for park and recreation facilities involves three levels: (1) system-wide master planning; (2) site planning for individual facilities; and (3) operational or maintenance planning.

While this chapter focuses on design and maintenance, success is heavily dependent on master planning, which should prioritize sustainability and environmental safety solutions. Master plans for parks should include a developmental history of the park system and changes it has undergone over time. Background information should define the planning area, planning process, and public engagement strategies. Site inventories using GIS mapping, site surveys, visits, and review of historical information can gather data on current environmental conditions, including historical features, environmental issues, soil conditions, vegetation, endangered species, topography, floodplains, wetlands, riparian buffers, and potential contamination from past agricultural or industrial use.

Permitted land uses should also be evaluated to determine if the intended use is allowed within the zoning code of the jurisdiction, together with all state and local ordinances for environmental and water quality protection. If the local jurisdiction does not own the land, deed restrictions or easements should be researched to determine any restrictions on land use, regardless of the landlord.

An inventory and analysis of recreation programs and park facilities may occur during site visits, focus group sessions, and interviews with municipal staff members, parks and recreation board members, and other recreation providers and stakeholders. This analysis identifies maintenance issues, risk management issues, and preventive maintenance needs.

Map data can be collected to determine current and potential future locations for parks, open spaces, and natural areas, as well as passive and active recreation sites. Any barriers associated with architecture, communication, transportation, or service that may limit use by people of various abilities should be identified and addressed through state or other acts, such as the Americans with Disabilities Act (ADA), with self-evaluation and the development of an action plan to overcome them.

When a strategic plan is in place and maintenance issues, preventive maintenance needs, and risk management issues are identified, soil-related aspects become a top priority. These include stormwater management, infiltration, and drainage; drainage and surface “skin” soil quality; grading issues; nutrient runoff/leaching control; compaction and aeration for turfgrass open areas; and maintenance issues for fertility, drainage, plant selection, and runoff.

To address human health and safety issues, ASTM Standards should be considered and incorporated into initial designs and maintenance plans for public spaces.

Case studies

The following case studies are examples of how stormwater management issues, drainage, runoff, and water quality in public areas have been addressed following identifying problems during strategic planning. The active consideration of ASTM standards was central in planning and design, but public opinion and function guided these innovative solutions.

High Line Park, New York City

Numerous case studies illustrate how particular cities have worked with both hardscape (the non-living, man-made elements of a landscape, e.g., pavement, buildings, walls, and other structures made of concrete, brick, or stone) and greenscape (the living, natural elements of a landscape, such as grass, trees, shrubs, and other plants) infrastructure solutions to create a system of dry and safe public areas. Soil analysis and management are the core of these systems. Parks, gardens, and green spaces are the first contacts for environmentally sustainable practices that city dwellers have within urban environments and the opportunity to provide for themselves and surrounding landscapes. Control of runoff and water quality from sealed lands (i.e., parking lots, roads, housing) and use of the space that was once an industrial or contaminated landfill have been taken on by cities through green space planning and sustainable maintenance to protect and conserve human health and welfare. The New York City High Line Park and transport corridor are prime examples of this ethic. The park is a green structure that repurposes formerly industrial infrastructure into a public space. Environmentally sustainable soil management is part of this highly successful renovation design and maintenance program, which took place between 2004 and 2009. Its fascinating history and development with NYC government and community support can be found with pictures at History | The High Line <https://www.thehighline.org/history/>.

Soil management on the High Line is integrated with plant selection, watering, pest management, and cleaning to produce a safe yet pleasing environment for thousands of tourists and locals who walk the Line daily. Planting beds contain formulated soil material that provides structure and consistency for adequate infiltration and a non-toxic stable planting medium. Native, drought-tolerant, and low-maintenance species sourced from a 100-mile radius make up the plant selection of the park, reducing the resources that go into the landscape and providing food and shelter for wildlife species (e.g., native pollinators). About 50% of the High Line's plants are native species, with many of them produced by local growers, making them more adaptable to the local climate, reducing the amount of plant failure and replacement costs. The gardens are diverse and ever-changing, with more than 15 distinct planting zones and 110,000 plants. The High Line's green roof system with drip irrigation allows the planting beds to hold as much water as possible. Combined with the drought tolerance of the High Line's plantings, the gardens need little supplemental watering. Garden waste is composted on-site, reducing the inputs to the waste stream and the need for energy-intensive transport to a separate compost facility. This, in turn, allows the recycling of essential nutrients in the soil to avoid supplemental fertilizer (Figs. 1 and 2).

The High Line, a public park in New York City, has implemented an integrated pest management program that relies on plant species well-suited to the climate to resist pests and disease. To avoid the use of pesticides in such a densely populated area, pests and infested plant materials are removed by hand. The park also prioritizes providing shelter for pollinators, such as wild bees, by

Fig. 1 Historical view of Highline railroad 2011 by Joel Sternfeld. <https://www.thehighline.org/history/>.

Fig. 2 The High Line park, NYC in winter. Photo by Anna Paltseva.

preserving fallen plant debris and dried stalks and stems, and incorporating as many native plants as possible. Additionally, the park mandates the use of eco-friendly cleaning solutions and post-consumer paper products for maintenance needs. Due to its elevated and narrow structure, the park faces challenges in snow removal following winter storms. Therefore, snow is removed by hand using shovels, power equipment, and eco-friendly ice melting products that are safe for the environment.

Camden Yards Sports Complex in the City of Baltimore, Maryland

Similarly, the Camden Yards Sports Complex in Baltimore, Maryland, underwent a \$5-million renovation of its pedestrian spine, known as Ravens Walk, to improve stormwater management while preserving the visitor experience. The project includes enhanced security features, new hardscaping, impervious surfaces, new landscaping, and stormwater improvements. The renovation was completed in 2019 and involved managing runoff from large parking lots to prevent parking lot contaminants from entering nearby waterways. This project is part of a larger trend of stormwater-centered investments by managers of professional sports venues across the United States, including those in Atlanta, Georgia; San Francisco, California; and Minneapolis, Minnesota (Figs. 3 and 4).

To improve stormwater management, several measures were implemented around the walkway at Camden Yards Sports Complex. The first step was to plant trees and small gardens to create a natural buffer against the flow from the parking lots. Additionally, an underground biofiltration system was installed, designed by Bio Clean Environmental Services (Carlsbad, California). Large drains were strategically placed to collect runoff, which then flows through a specialized filtration medium that simulates a natural wetland's absorption power. This treatment process helps remove pollutants, and the treated stormwater flows at a controlled rate into the surrounding area, meeting pollutant-removal benchmarks without requiring any input from surface-level plants. To provide comprehensive stormwater management with minimal above-ground infrastructure, five of these biofiltration units were installed around the Pedestrian Spine.

An innovative, underground biofiltration system helps the walkway discourage flooding and prevent water pollution. Image courtesy of Bio Clean Environmental Services.

Fig. 3 Trees and Gardens planted as natural buffer from parking lots at Camden Yards. Image courtesy of Anna Paltseva.

Imitated natural marshland in Southeastern Louisiana

Southeastern Louisiana University (Mandeville, LA) provides an excellent example of a relatively low-tech solution for imitating natural marshlands to treat freshwater ponds and water features contaminated by stormwater runoff. By using softscape techniques derived from soil conservation and reclamation strategies for shoreline erosion and buffer strips, marshland technology aims to improve water quality throughout St. Tammany parish in Louisiana.

Within the Del Sol subdivision of Covington, LA, a star-shaped, eight-armed frame of polyvinyl chloride piping with 1.2-m (4-ft) wide, vinyl-coated crab wire between the piping acts as a platform and supporting structure for marsh plants such as maidencane, arrowhead, and spider lily. The plants are attached to the netting, forming a natural filtering mechanism for the pond water. The artificial floating marsh removes excess nutrients and turbidity caused by fertilizers, pesticides, and herbicides. This project demonstrated an improvement in water quality in the first year, becoming much clearer with a considerable reduction in turbidity. Additionally, the marshland frames create a habitat for minnows and juvenile fish, significantly improving the ecosystem functioning of the pond.

Fig. 4 Underground drainage system at Camden Yards. Image courtesy of Anna Paltseva.

Similar applications have great potential for sustainably creating a more natural ecosystem associated with water features in golf courses or stormwater retention ponds in parks and open spaces. Similar structures have been experimentally installed in harbor public land viewscapes such as in the harbor of the City of Baltimore to improve water quality, fish nursery habitat, and public awareness (Fig. 5).

Soil considerations for sports fields, public access and open spaces

Sport fields—Pitches

A pitch's surface can be made of sod (grass), artificial turf, sand, clay, gravel, concrete, or other materials. Pitch care or turf management refers to the maintenance work required to keep a sporting pitch ready for use. Different types of sporting pitches present unique challenges, and the protocols and specifications for maintenance vary considerably depending on the sport and the use of artificial surfaces. Unique skill sets and approaches based on the soil are also needed to care for sand-based athletic fields or native soil fields. In most cases, regardless of the sport, there are four main attributes of a good grass pitch: good drainage, adequate grass coverage, a flat surface, and a low level of weeds.

Historically, soccer and American football pitches have had natural grass covers. However, the stresses on a pitch and winter weather lead to the pitch being returfed regularly. Typically, the existing turf is removed to a depth of 40 mm turf and 110 mm of soil, and the replacement turf is grown to ensure consistency and weed-free ground. A pitch can be returfed within four days, which involves removing and re-laying 400 cubic meters of turf and soil.

Football pitch technology has advanced considerably since the 1970s and 1980s, when almost all pitches turned into mud baths by December. Nowadays, technology includes drainage pipes at 5 m spacing, a gravel raft, a sand (suspended water table) rooting zone, undersoil heating, and additional lighting on the surface stimulating growth. Management techniques have also advanced, with more emphasis on soil and plant biology, morphology, zoology, and physiology being introduced into turf grass and soil management. There are lots of materials and methods available to reinforce a natural grass playing surface. Artificial grass offers an alternative to natural grass for football stadiums. The performance of this surface has often been questioned as not being truly natural. However, artificial grass has definite advantages, especially when a stadium has heavy or multi-use requirements. Artificial grass also has a benefit in settings hostile to natural grass, such as low sunlight intensity or water scarcity (Fig. 6).

The key specifications for surface “skin” soil management of recreational areas developed for the United States are summarized in Table 1. The specifics of these guidelines are beyond the scope of this chapter.

Fig. 5 Baltimore Harbor creates habitat for minnows and stabilization, water quality features similar to that described in pilot project in Southeastern Louisiana. Photo by Maxine Levin.

Table 1 Major ASTM specifications and guidelines for surface soil management considerations on sports fields and playgrounds^a.

Guideline	Content
ASTM F 2107-08 (2020) Standard Guide for Construction and Maintenance of Skinned Areas on Baseball and Softball Fields	This guide covers techniques that are appropriate for the construction and maintenance of skinned areas on baseball and softball fields. This guide provides guidance for the selection of materials, such as soil, sand, gravel, crushed stone, crushed brick, calcined clay, diatomaceous earth, vitrified clay, etc., for use in constructing or reconditioning skinned areas and for the selection of management practices that will maintain a safe and playable skinned surface. Although this guide is specific to baseball or softball, it has application to other sports where ball bounce, ball roll, or player footing, or a combination thereof, are of importance
ASTM F 2270-12 (2018) Standard Guide for Construction and Maintenance of Warning Track Areas on Sports Fields	This guide covers techniques that are appropriate for the construction and maintenance of warning track areas on sports fields. This guide provides guidance for the selection of materials, such as soil and sand for use in constructing or reconditioning warning track areas and for selection of management practices that will maintain a safe and functioning warning track. Although this guide has applications to all sports where a warning track surface may be required or desired, it has specific applications to baseball/softball
ASTM F 2000-19 Standard Guide for Fencing for Baseball and Softball Fields	This guide provides recommended minimum requirements for various types of fences used in softball and baseball ballfields and other sports facilities, and practices for installation
ASTM F 1938-98 (2017) Guide for Safer Use of Movable Soccer Goals	This guide presents directions for the installation, use, and storage of full-size or nearly full-size movable soccer goals. It is expected that these guidelines can help prevent deaths and serious injuries resulting from soccer goal tipover. These guidelines are intended for use by parks and recreation personnel, school officials, sports equipment purchasers, parents, coaches, and any other members of the general public concerned with soccer goal safety
FIELDS—NATURAL GRASS/ROOTZONE	This guide covers techniques that are appropriate for the construction of high performance sand-based rootzones for sports fields. This guide provides guidance for the selection of materials, including soil, sand, gravel, peat, and so forth, for use in designing and constructing sand-based sports turf rootzones
ASTM F 2396-11 (2019) Standard Guide for Construction of High Performance Sand-Based Rootzones for Sports Fields	
ASTM F 1632-03 (2018) Standard Test Method for Particle Size Analysis and Sand Shape Grading of Golf Course Putting Green and Sports Field Rootzone Mixes	This test method covers the determination of particle size distribution of putting green and other sand-based root- zone mixes. Particles larger than 0.05 mm (retained on a No. 270 sieve) are determined by sieving. The silt and clay percentages are determined by a sedimentation process, using the pipet method. This procedure was developed for putting green rootzone mixes, those assumed to have sand contents of 80% by weight or greater. Particle size analysis of soils may be performed by this test method or Test Method D 422. This test method also describes a qualitative evaluation of sand particle shape
ASTM F 1647-11 (2018) Standard Test Methods for Organic Matter Content of Athletic Field Root Zone Mixes	These test methods cover the determination of the percent organic matter of a putting green root zone mixture using a loss on ignition method or the Walkley Black method. These test methods are useful for quantifying the organic matter content of volume ratio mixed root zone mixes. Test Methods D 2974 is recommended for peat and other organic soils
ASTM F 1815-11 (2018) Standard Test Methods for Saturated Hydraulic Conductivity, Water Retention, Porosity, and Bulk Density of Athletic Field Root Zones	These test methods cover the measurements of saturated hydraulic conductivity, water retention, porosity (including distribution of capillary and air-filled porosity at a known soil suction), and bulk density on sand-based root zone mixes to be used for construction and topdressing of golf course putting greens including United States Golf Association (USGA) recommended greens, golf course tees, sand-based sports fields, or other highly trafficked turfgrass areas. These test methods are designed for sand-based mixes and are not intended for use with fine or medium textured soils, for example, sandy loams and loams
ASTM F 2060-00 (2018) Standard Guide for Maintaining Cool Season Turfgrasses on Athletic Fields	This guide covers the minimum requirements for maintaining cool season turfgrasses used for natural surface athletic fields. Practices covered include mowing, fertilizer application, irrigation, core cultivation, overseeding, and pest management
ASTM F 2269-11 (2018) Standard Guide for Maintaining Warm Season Turfgrasses on Athletic Fields	This guide covers the minimum requirements for maintaining warm-season turfgrasses used for natural surface athletic fields. Practices covered include mowing, fertilizer application, irrigation, core cultivation, winter overseeding, pest management, and requirements for management of dormant turf winter overseeded with cool-season turf (see also Guide F 2060)
FIELDS—SYNTHETIC TURF	These test methods establish a recommended list of test methods to be used for the identification of physical property characteristics and comparison of the performance properties of synthetic turf systems or components for athletic and recreational uses, or both
ASTM F 1551-09 (2017) Standard Test Methods for Comprehensive Characterization of Synthetic Turf Playing Surfaces and Materials	
ASTM F 2765-014 Standard Specification for Total Lead Content in Synthetic Turf Fibers	This specification applies to the maximum content of lead in fibers used in synthetic turf. This specification outlines a test method for sample preparation and a test method for analyzing the total lead content in synthetic turf fibers. This specification outlines guidelines for reporting total lead content in synthetic turf fibers. This specification applies only to synthetic turf fibers manufactured after September 1, 2009. Note 1—It is the goal of the industry to reduce lead content to 100 mg/kg (ppm) by September 1, 2011

(Continued)

Table 1 (Continued)

<i>Guideline</i>	<i>Content</i>
ASTM F 1015-03 (2017) Standard Test Method for Relative Abrasiveness of Synthetic Turf Playing Surfaces	This test method is applicable to both laboratory and field measurement of synthetic turf surfaces used for sports. Data obtained from the procedure of this test method are indicative of the relative abrasiveness of fabric or carpet type synthetic playing surfaces
ASTM F 2898-11 (2019) Standard Test Method for Permeability of Synthetic Turf Sports Field Base Stone and Surface System by Non-confined Area Flood Test Method	This test method may be used to determine the permeability rate of synthetic turf playing field systems, playing field systems with pad or premolded drainage boards, or both, playing field systems with premolded panel base systems, porous and non-porous pavement systems, or base stone systems in the field, or a combination thereof, by non-confined area flood test method. This system is suitable for use on the finish synthetic turf playing surface and on the stone base system below the playing system
FIELDS—IMPACT ATTENUATION	This test method covers the measurement of certain shock-absorbing characteristics, the impact force-time relationships, and the rebound properties of playing surface systems. This test method is applicable to natural and artificial playing surface systems and to components thereof. Typical playing surfaces are wrestling mats, football fields, soccer fields, playgrounds, and so forth
ASTM F 355-16e1 Standard Test Method for Impact Attenuation of Playing Surface Systems, Other Protective Sport Systems, and Materials Used for Athletic, Recreation and Play	
ASTM F 1936-19 Standard Specification for Impact Attenuation of Turf Playing Systems as Measured in the Field	This specification establishes an in situ test method and maximum impact attenuation value for all types of turf playing systems and for a number of sport-specific field layouts. It also includes a protocol for determining test point locations on fields that are lined for multiple sports
ASTM F 1702-10 (2018) Standard Test Method for Measuring Impact-Attenuation Characteristics of Natural Playing Surface Systems Using a Lightweight Portable Apparatus	This test method is used to determine the impact-attenuation characteristics of natural turfgrass and soil playing surface systems with a lightweight portable apparatus. This test method can be used to compare the impact attenuation characteristics of natural playing surface systems, as well as assessing the effects of management practices on the impact attenuation characteristics. This test method also can be used to assess the compactibility of natural playing surfaces by recording g-max values or penetration of successive impacts, or both. This test method provides a procedure for assessing impact attenuation characteristics in the field, on both actual playing surfaces and research plots. Numerical data will not be comparable to data obtained using a different missile mass or geometry, different drop height, or different standard method, for example, Test Method
ASTM F 2650-17e1 Standard Terminology Relating to Impact Testing of Sports Surfaces and Equipment	This terminology covers terms related to impact test methods and impact attenuation specifications of sports equipment and surfaces

^aThe complete list and guidance documents are available electronically through the ASTM International website or American Sports Builders Association. Relevant ASTM Standards—Fields (sportsbuilders.org) <https://sportsbuilders.org/page/RelevantASTMStandards-fields>).

Vegetation cover on golf courses

The increasing popularity of golf has led to the development of turf management, which refers to the skills needed to maintain a golf course. The green and tee box are the principal areas of concern, and many golf courses are now built in environments that are hostile to natural grass cover. Essentially, the grass grows in a hydroponic or sterile environment with speedy drainage, requiring regular feeding and watering. The key characteristics of a good green are speed and consistency. Faster greens are preferred, and for tournament play, the greens should be as fast as possible. The main factors influencing green speed are:

- Mowing height, which today is typically between 3 and 6 mm. Top courses are striving for even lower cutting heights due to the demand for faster greens. In the 1960s, green mowers were not capable of cutting below 6 mm, but nowadays, they can cut below 3 mm.
- Frequency of mowing. During the growing season, daily mowing is required. For faster speeds and professional tournaments, greens may be cut twice a day or even double cut (two cuts in two directions, one immediately following the other).
- Rolling can also improve green speed, but excessive rolling can compact the soil.
- Topdressing helps with consistency and reduces thatch buildup.
- Grooming reduces the thickness of clumps.
- Verticutting removes excessive thatch, forces the grass blades to stand upright, thins out excessive growth, and speeds up greens.
- Scarification removes moss and prevents moisture collection on the green.
- Beneficial bacteria, fungi, and nematodes are used as stand-alone applications or in integrated programs to control key turf pests and diseases.
- Aerating removes excessive organic matter, modifies the rootzone composition, and improves rooting and drainage.

The rough and fairway present the best opportunity for sustainable, clean, and green maintenance in golf course design. Functionality is more about the practical attributes of the turf, such as playability, slope stabilization, or runoff reduction. Performance equals aesthetics and function. Expectations vary widely, and each management scenario may prioritize different aspects of turf performance:

- Example #1, a high-end private golf course: aesthetics and function are likely to be top priorities. Such sites are managed for maximum playability and are simultaneously expected to be green and manicured in appearance.
- Example #2, an earthen dam: appearance takes a back seat in favor of efforts to ensure that a hardy, perennial cover is in place to minimize the potential for adverse runoff or soil erosion.

Golf course planning can use the fairway and sightline, as well as the rough, water features, and sand traps, to take on aspects of the natural landscape and add to the sustainability outcomes with low maintenance and water needs, water and sediment retention, and no inputs for fertilizer and pesticides. These features allow for the propagation of native species and pollinators without sacrificing function on the high-maintenance tee box and greens.

Soil quality and potential problems

Understanding types of drainage

Evaluating drainage on a local scale, such as in gardens and sports fields, requires an assessment of the ability of the surface soil to drain water. Natural drainage from the soil profile drives any design alterations needed to create dry surfaces for play and maintenance of green space. There are two types of drainage to consider: sub-surface and surface.

Sub-surface drainage is important to prevent water from accumulating on the surface of unsealed fields during heavy rain. This is typically achieved by adding a layer of mixed gravel or cinders about 45–60 cm below the surface of the seedbed. This layer has high porosity, allowing moisture to be swiftly moved away from the playing area. However, it also prevents moisture from moving up from below the surface. Proper irrigation facilities can minimize the need for upward movement of moisture, and the adverse effects of sub-surface drainage are negligible.

Surface drainage is achieved by maintaining an even surface level, free of compaction and depressions that can cause standing water to pool. The standard is to create a slightly sloping surface of about 1–1.5 cm per meter to allow for surface runoff and maximum infiltration. This technique has been used throughout the United States as a standardized manner of preparing surfaces for well-drained yet green sports fields.

The importance of soil quality and organic matter content

In addition to considering the drainage and surface grading, it's also important to pay attention to the quality of the soil "skin" of a playfield or pitch (field of play), especially if there is green turf. The soil quality and organic matter content affect infiltration and seedbed viability, which can impact player safety. The composition of the seedbed is critical because it will be exposed to the elements and heavy impacts. Ideally, the seedbed should consist of around 10%–15% organic matter, 10%–20% coarse sand, 10% clay, and the remaining sandy loam with clay content not exceeding 15%.

Soil aeration and compaction-soil management and cultivation

Soil management and cultivation is crucial for maintaining healthy soil for plants to grow. Aeration, which involves replacing soil air with air from the atmosphere, is essential in sustaining adequate soil oxygen for root growth and other growth-related activities. However, soil compaction caused by vehicular and foot traffic in parks, sports fields, golf courses, public thoroughfares, and right of ways can be a major contributor to poor aeration, leading to turf management problems and alterations in the physical properties of the soil.

Soil compaction can decrease the total pore space, reducing macropore (large) spaces that are essential for internal drainage, channels for root growth, and air exchange, while increasing micropore (small) spaces that retain water. The latter can also reduce the soil oxygen content, which is necessary for root respiration and growth, and limit nutrient uptake by roots. Furthermore, compacted soils can reduce water infiltration and percolation rates, leading to changes in irrigation practices and scheduling.

Compaction increases soil strength and density, which can reduce rooting density and depth. Additionally, it can increase water retention, prolonging wet soil conditions and delaying spring green-up by delaying soil warming, and intensify compaction in trafficked areas. In contrast, dry compacted soils in summer warm up faster and promote high soil temperatures, dramatically slowing root growth. Therefore, it is important to manage and cultivate soil to prevent soil compaction and promote adequate aeration for plant growth.

Compaction and turfgrass cultural intensity

Soil-related stresses caused by soil compaction can negatively affect the growth of turfgrass, leading to the need for changes in management practices. Different cultivation methods are available to turfgrass managers, including coring techniques such as hollow tine, solid tine, or shatter coring, slicing, and spiking. However, these methods differ in their effectiveness in achieving important cultivation objectives, such as thatch removal, alleviation of soil compaction, and preparations to enhance seed-soil contact for overseeding purposes. Power raking and vertical cutting may reduce thatch but do not reduce soil compaction, which is the primary issue. Hollow tine and solid tine coring methods minimize soil compaction and alleviate thatch by promoting aeration and new growth. Slicing and spiking, commonly used on golf courses, do not improve soil aeration to the same extent as core cultivation practices but are less disruptive to putting surfaces. Coring, especially hollow tine, is more disruptive to surface uniformity and requires a more extended period for recovery. However, it is the most effective method for improving aeration and alleviating compaction. A relatively new technology that uses short bursts of water injected under high pressure has been shown to reduce compaction and improve aeration, equal to or better than hollow tine core cultivation, with less surface disruption.

Soil compaction often necessitates increased fertilizer and pesticide or herbicide use. Low shoot density encourages encroachment of weedy species tolerant of compacted sites, such as annual bluegrass, goosegrass, and knotweed, resulting in greater herbicide use and cost. Reduced turfgrass vigor and favorable moisture conditions can lead to disease activity with brown patch and Pythium blight. Turfgrass nutrient uptake from compacted soils may be reduced by 10%–30%, leading to chlorotic, nitrogen-deficient turf. Additional nitrogen further reduces rooting potential because the symptoms may not necessarily be due to nutrient deficiency but somewhat limited root activity and viability.

Irrigation efficiency drops due to low infiltration rates associated with compacted sites that may promote pooling (ponding) and surface water runoff, reducing the amount of water available to recharge the root zone. Typically, multiple cycling of irrigation water (small amounts of water applied over an extended period using several irrigation events) must be practiced, complicating irrigation scheduling. Due to poor drainage and restricted rooting, small doses of water must be applied more frequently, creating wetter conditions that intensify compaction.

In addition, soil compaction encourages plant tissues to become more succulent and have lower carbohydrate levels (a condition associated with poor drainage and frequent irrigation), reducing environmental stress tolerance (heat, cold, drought, disease, wear). Any factor that contributes to increased tissue succulence (e.g., excess nitrogen, water, shade, and close mowing) combined with compaction will reduce root and shoot response more than any of these factors when considered alone. Additional maintenance is required to reduce or eliminate the symptoms.

With intensive maintenance on groomed tee boxes and greens in golf courses, alleviating soil compaction and improving aeration can have various positive effects, such as the release of gases such as CO₂ (which begins immediately after coring), increased soil infiltration rate, enhanced rooting within core aerifier holes (within 2–3 weeks after coring), decreased thatch accumulation following core cultivation, and increased fertilizer uptake and use due to aeration. Aeration also promotes incorporation of immobile materials such as lime and phosphorus into the root zone.

In summary, soil compaction can have significant negative effects on turfgrass health, and proper cultivation methods such as coring can help alleviate these issues. Improved aeration can have numerous positive effects on turfgrass maintenance, including improved nutrient uptake and irrigation efficiency.

Turfgrass drought survival

When rainfall is insufficient, and water resources become limited, supplemental irrigation is often required to sustain turf growth. Under rainfall deficit conditions, irrigation of landscape plantings such as turf is often among the first activities to be placed on

water use restrictions. In this case, maintaining functional and high-quality turf with less water is required. Guidance from drought-prone areas can inform any area of the country or world to conserve water and yet maintain visual green sightlines and targeted sport function. Conservative irrigation management through drip and selective watering, controlling drainage and runoff, and managed native buffer space are critical for water quality protection. Water conservation strategies are routinely practiced in semi-arid and arid regions such as the southwest desert of the United States. These strategies include (1) incorporating water-use-efficient plant material into the landscape, (2) implementing water-conserving management practices, and (3) maximizing irrigation efficiency by controlling leaching, pooling, or ponding of irrigation water and surface water runoff. The following information from University of Massachusetts Turfgrass extension is a good example of taking specific recommendations from the desert and applying them to drought conditions.

Management tips to improve turfgrass drought survival

1. Mowing and nutrition

To promote healthy turf growth and drought survival, mow at the higher end of the recommended mowing height range for your species and cultivars (around 5–7.5 cm). This will create shade on the soil surface, encourage deeper root growth, and better water retention. Use nitrogen fertilizer in moderation, with at least 30% slow-release nitrogen. During drought conditions, avoid fertilizing non-irrigated turf. Excessive nitrogen can promote fast shoot growth rates and more drought-sensitive tissues, and reduce root depth and number. A moderate green color is healthier than a dark green color. In the fall, make sure to have adequate phosphorus and potassium levels (based on a soil test) to encourage drought recovery. If there is no potassium deficiency, apply potassium at about 50%–75% of the nitrogen applied.

2. Water or irrigation efficiency

To prevent surface runoff and puddling, apply water at a rate that the soil can absorb it. Apply only the amount of water that can be stored in the root zone without leaching. Check the rooting depth of the soil using a garden trowel, shovel or soil probe. In Massachusetts, most turfgrass species require 2.5–3.8 cm of water per week. For low traffic areas where wear tolerance is not a major concern, schedule irrigation to allow for mild to moderate stress (indicated by wilting and leaf rolling or folding) between watering events to promote deeper rooting and drought survival. Avoid over-irrigating as it can cause succulent growth, depletion of soil oxygen, and soggy conditions leading to soil compaction. Address issues that reduce soil infiltration rates like soil compaction, thatch, and hydrophobic soils to improve irrigation efficiency in the fall.

3. Control root-related stresses in the spring and fall

- Soil pH—maintain pH between 6.0 and 7.0 because root growth and activity are limited below pH 5.5 and above pH 7.5.
- Compaction—manage compaction to maximize rooting potential by maintaining optimum aeration (soil oxygen content) and gas exchange (to limit toxic CO₂ levels), minimizing water logging, and prolonging soil wetness.
- Apply herbicides intelligently—preemergence herbicides are more toxic to roots than to shoots. Hence, turfgrass shoots may be unaffected while root activity is severely reduced. An herbicide should be applied only as needed and according to label directions. Spot treat for broadleaf weeds when possible, to limit stress and avoid blanket applications when air temperatures exceed 29.4 °C.
- Thatch—manage thatch to keep levels below 4 cm to promote deeper rooting into the soil and limit rooting confined to the thatch. Thatch generally has poor nutrient and water-holding characteristics.

Brown or straw colored (dormant) lawn-turf strategies

During prolonged periods of little or no water (from precipitation or irrigation), grass growth will cease, resulting in a straw-colored turf. However, the perennial parts of the plant, including crown tissues near or at the soil surface, and nodes on lateral stems (rhizomes and stolons), remain active and capable of regenerating new shoots and roots when there is significant rainfall. With normal summer dormancy, recovery and green-up may take 2 weeks or more, and 100% green-up may not be achieved following extended periods of dormancy (45 to 60+ days) with little or no rainfall. Timely watering and proper management, as previously outlined, can help avoid drought-induced dormancy if high-quality and functional turf is desired.

Additional strategies for dormant turf

- Mowing—don't mow unless necessary to reduce stress; mow high and infrequently; avoid mowing mid-day, late afternoon, and early morning are preferred; use a sharp mower!
- Nutrient application—consider a drought fertilizer application program in the fall to enhance recovery; superior root and stem development (rhizome and stolon) are critical for recovery, and low nitrogen and high potassium rates are helpful (i.e., 15-0-30 type or similar analysis); avoid straight nitrogen applications.
- Irrigation—if irrigation cannot be applied properly and on a timely basis it is preferred to allow the turf to enter dormancy (buds associated with crowns and lateral stems are extremely drought hardy); unirrigated turf in a dormant state produces a

healthy turf in a short time after drought ceases; watering improperly during drought-induced dormancy accelerates the depletion of carbohydrate reserves which reduces drought-recovery potential.

- Pest problems—inspect for disease (summer patch) and insects (chinch bugs) regularly which may go undetected when the turf is dormant and not actively growing; weed pressure and numbers may increase, which compete for limited soil moisture, reduce herbicide usage (spot treat for weeds) during dormant periods.
- Renovations—consider renovations in the fall if drought recovery is poor or thatch levels are excessive (2.5 cm).

Nutrient management

First and foremost, in any evaluation and prescription for best management practices, whether “green and clean” or traditional aesthetic:

- Read the landscape and analyze site and soil conditions;
- Implement proper grading techniques;
- Evaluate soil conditions for plant selection;
- Identify different types of soil and learn how water moves through each; and
- Apply the right tools and techniques to solve drainage, compaction and fertility issues.

The development and implementation of a nutrient management plan (NMP) is critical to sustainable maintenance, with a priority on environmental protection and enhancement. An effective NMP should address sound agronomic practices that promote healthy turf, gardens, and fields, while also protecting water bodies. The following guidelines outline the components of an NMP that can be adapted to a variety of turf management systems. For instance, UMass Extension’s Best Management Practices for Lawn & Landscape Turf manual provides detailed coverage of the components of an NMP specific to lawn turf management in Section 7. This manual can be accessed online at <http://extension.umass.edu/turf/publications-resources/best-management-practices>. Although the manual focuses on lawn and landscape turf, the presented information can be applicable to the management of other types of parkland or right of ways, such as high-value playing surfaces or shallow maintenance turf areas.

A complete NMP should include:

Site analysis and mapping, such as:

- Identification and mapping of environmentally sensitive areas and areas at high risk for off-site movement of nutrients.
- Mapping specific buffer zones delineated in environmentally regulated areas (e.g., Zone I wellheads, wetlands, and certain coastal zones), and for the protection of environmental resources.
- Mapping of areas receiving fertilizer or amendments containing nutrients.
- Soil tests to determine the chemical and physical condition of the soil and ascertain recommendations for adjustments.

Determination of need for nutrient inputs based on soil testing, turf function and quality desired, and proximity to environmentally sensitive sites such as:

- the lowest input rate of nitrogen, phosphorus, and other nutrients will produce dense turf cover and promote deep rooting.
- form (source) of nutrients appropriate for the management plan and the use of the turf on the site.
- appropriate placement of fertilizer and amendments containing nutrients.
- application frequency of fertilizer and amendments containing nutrients based on the nitrogen and phosphorus characteristics of each material.
- timing of fertilizer applications so that maximum nutritional availability corresponds with periods of active turfgrass growth.
- fertilizer and amendments containing nutrients should not be applied before spring green-up or when turf is dormant.
- fertilizer and amendments containing nutrients should not be applied when the ground is frozen.
- fertilizer and amendments containing nutrients should not be used as de-icers.
- Ample available phosphorus (P) is critical to the success of turf establishment, renovations, and major repairs. P levels applied in conjunction with such activities should be adequate for rapid turfgrass germination, growth, and development. Specific considerations for phosphorus (P):
- determination of P levels by a soil test, and where and when the application of phosphorus-containing materials may and may not be allowed by state or local regulations.
- application of phosphorus-containing fertilizers and other nutrient-containing materials, regardless of the source of nutrients or the purpose of the application, should not exceed levels recommended by a soil test.
- accounting for all phosphorus inputs into the management program and turf system, such as fertilizers, turfgrass clippings retained in the system, composts, compost derivatives and other organic amendments, topdressings and other materials.

Considerations for nitrogen (N)

- determination of nitrogen (N) need based on turfgrass species, time of year, turf vigor, plant response, and frequency of turf use.
- determination of N rate based on turf needs as influenced by turf function and use as well as by presence of and proximity to environmentally sensitive areas, keeping N level to the lowest possible required to realize management objectives while protecting the environment.

- use of slow-release sources of N as often as possible based on management objectives.—Accounting of all N inputs into the management program and turf system. These may include fertilizers, retained turfgrass clippings, composts, compost derivatives and other organic amendments, topdressings, corn gluten used as an herbicide or fertilizer; and carryover N from prior seasons.

Plant selection based on soil pH to minimize need for fertilizer and pH adjustment

Plants require specific pH levels for optimal growth. For most ornamental plants, a pH range of 6.0–7.0 is ideal. However, some plants such as azaleas, gardenias, camellias, and related species can tolerate lower pH levels between 4.5 and 5.5. As stated above, turfgrass species, on the other hand, require a pH range of 5.5–7.0 for optimal nutrient uptake and performance. For more information on the optimal pH ranges for ornamental flower trees and bushes, you can refer to Fact Sheet 372 by Mississippi State University Soil pH and Fertilizers | Mississippi State University Extension Service (msstate.edu) Turf species range of pH are listed in Tables 2 and 3 (Bill's Will, 2017).

Adjusting soil pH through the use of lime, sulfur, or fertilizers is feasible to some extent, depending on soil texture, organic matter content, and buffering capacity. However, this method is not always a long-term or effective solution for maintenance, and it may require additives that can negatively impact water quality in runoff and leachate. Furthermore, adding lime to increase soil pH levels may increase the levels of native heavy metals such as arsenic (As), cadmium (Cd), or chromium (Cr), potentially affecting the

Table 2 Soil pH for grass types.

Grass pH ranges	pH-LOW	pH-HIGH
Bahiagrass (<i>Paspalum notatum</i>)	6.0	7.5
Argentine—Pensacola—Tifton-9		
Bentgrass (<i>Agrostis</i>)	5.6	7.0
Colonial and Creeping		
Bermuda (<i>Cynodon dactylon</i>) Hybrids and Common	5.6	7.0
Bluegrass (<i>Poa pratensis</i>)	5.7	7.4
Buffalo (<i>Bouteloua dactyloides</i>)	5.6	7.0
Carpetgrass (<i>Axonopus aureus</i>)	6.0	8.0
Centipede (<i>Eremochloa ophiuroides</i>)	4.3	5.8
Fescue (<i>Festuca rubra</i>) Red and Creeping	5.6	6.8
Fescue Tall (<i>Festuca arundinacea</i>)	5.6	7.0
Rye Annual (<i>Lolium multiflorum</i>)	5.8	7.4
Perennial Rye (<i>Lolium perenne</i>)	5.8	7.4
St. Augustine (<i>Stenotaphrum secundatum</i>)	6.3	7.8
Zoysia	5.5	7.0

Grass types with the lowest and highest pH level tolerated.

Table 3 The power of pH

Turfgrass	Soil pH tolerance	Ideal soil pH
<i>Warm season grasses</i>		
St. Augustine (<i>Stenotaphrum secundatum</i>)	5.0–8.5 ^a	5.5–7.2
Centipede (<i>Eremochloa ophiuroides</i>)	4.5–7.2	5.0–5.5
Bermuda (<i>Cynodon dactylon</i>)	5.5–7.5	6.0–7.0
Zoysiagrass (<i>Zoysia</i>)	5.0–7.8	6.0–6.5
Buffalo grass (<i>Bouteloua dactyloides</i>)	6.0–8.0	6.0–7.0
Seashore Paspalum (<i>Paspalum vaginatum</i>)	4.5–9.0	5.5–8.0
<i>Cool season grasses & soil pH</i>		
Kentucky Bluegrass (<i>Poa pratensis</i>)	6.0–7.2	6.0–7.2
Perennial Ryegrass (<i>Lolium perenne</i>)	6.0–7.5	6.0–7.0
Creeping Bentgrass (<i>Agrostis stolonifera</i>) (golf course greens)	5.5–7.2	5.5–6.5
Tall Fescue (<i>Festuca arundinacea</i>)	4.7–8.5	5.5–6.5
Fine Fescue (mix- <i>Festuca rubra</i> , <i>Fescue brevipila</i> , <i>Fescue ovina</i> L)	5.5–7.0	5.5–6.5

^aIron Chlorosis develops over pH of 7.5.

Adapted from The power of pH (2018).

biological components of otherwise healthy soils. A more sustainable approach is to utilize plant species that are best suited to the native pH of the soil for maintaining green vegetation.

Implementation of cultural practices that maximize nutrient uptake by plants, reduce nutrient waste and reduce off-site movement of nutrients. These practices include:

- minimization of bare soil and maintenance of dense turf cover to reduce erosion, prevent runoff and increase nutrient retention within the turf/soil system.
- Implement practices that result in rapid turf establishment following new planting or repairs.
- application of fertilizer and amendments containing nutrients only to turf, avoiding designated environmentally sensitive areas.
- application of fertilizer and amendments containing nutrients in a manner that prevents entry into surface waters or conduits, for example, catch basins that lead to surface waters or other environmentally sensitive areas.
- application of fertilizer and amendments containing nutrients where intended and not on hardscapes (driveways, sidewalks, roadways, non-vegetated surfaces). Should materials inadvertently land on such surfaces, they should be removed promptly and handled properly.
- handling of turfgrass clippings in an appropriate manner:
- retention of clippings within the turf system whenever possible.
- management of turfgrass clippings so that they are not allowed to enter surface waters or conduits such as catch basins that lead to surface waters.
- clippings that are removed should be composted or handled in a manner that does not threaten the environment.
- mowing at the highest end of the proper mowing height range for the grasses and cultivars present and for the turf use to maintain turf density and maximize rooting.
- irrigation practices promote infiltration and plant uptake, do not lead to runoff and leaching, and encourage deep and extensive turfgrass rooting.
- relief of compaction through appropriate cultural practices such as core aeration.
- Implementation of proper storm water management techniques aimed at reducing off-site movement of soil and nutrients.

Detailed application records for inputs of fertilizer and nutrient-containing materials. Field management teams recommend having soil tested when constructing a new field for fertility purposes and periodically once the field is established. If minerals are lacking, fertilizers can be applied 7–10 days prior to seeding and should be raked into the upper 5–7.5 cm of the topsoil.

Certain functional aspects of different turfgrass species and varieties may aid the turf manager in reducing inputs to meet specific management objectives. For example, grasses with lower consumptive water use rates may perform better under drought conditions while at the same time conserving irrigation water. Endophytic grasses may reduce damage from surface-feeding insects, and in turn, reduce the need for insecticide applications.

The science behind turf management

Future studies on sustainable turf-based public areas should consider public opinion and aim to achieve attainable human health outcomes while maintaining clean and green environments. Several studies have investigated the effects of turf management practices, including greenhouse gas emissions and fertilizer applications. For example, a study conducted by the University of Minnesota Crookston on Kentucky bluegrass turf found that while fertilizers increased turf health and greenness, they also increased greenhouse gas emissions, particularly during urea application. Researchers recommended the use of slow-release fertilizers such as Milorganite to lower emissions and maintain healthy turf. The study also considered cultivation practices such as verticutting and hollow tine aerification. It was observed that plants that had been aerified had higher emission rates than those that were untreated, while verticutting led to lower emissions, especially of CO₂ and N₂O, but decreased overall turfgrass quality.

The University of Massachusetts Extension Turf program has produced an extensive manual of Best Management Practices for turfgrass, which focuses on environmental protection and human safety for use with lawns and public space functions. The information presented in this guide, BEST MANAGEMENT PRACTICES FOR LAWN AND LANDSCAPE TURF version 1.51, is research-based and expertly audited knowledge intended to help practitioners make informed decisions focusing on scientific principles and practices of integrated pest management (IPM). For established, healthy turf, the guide recommends conducting soil chemical analyses at least every three years and monitoring pH annually. Critical soil test results for optimum growth have been summarized for US New England states turfgrass management, as well as recommendations for proper plant selection and optimum match with soil pH.

Another study, conducted at the University of Tennessee, aimed to determine the effect of soil type and grass species on head injury criterion (HIC). Soil moisture content was also considered and divided into three categories: dry (0.06–0.16 m³/m³), acceptable (0.17–0.29 m³/m³), and wet (0.30–0.40 m³/m³). The analysis used the Clegg hammer, a 2.25 kg hammer, to measure the surface hardness and the F334-E missile. The results of the study suggest that grass species have a minimal impact on HIC threshold, but soil type makes a significant difference. Of all the types analyzed, the USGA sand root zone was proven to be the optimum root zone for minimizing head injury risk to players. These root zones also suffered the least adverse effects due to water levels.

Park soil contamination and remediation

Soil contamination is a serious threat to human health globally, with heavy metals being a common source of pollution. Heavy metal contamination can result from industrial activities, gasoline emission deposits, lead paint, traffic, mining activities, among others, which can contaminate both industrial and residential areas. The potential health risks from exposure to heavy metals in contaminated soils were explored in various studies.

A study conducted near Athens, Greece, which converted a former shooting range into a public park, found concentrations of lead, nickel, and zinc using a portable X-ray Fluorescence Spectrometer (XRF). The study also explored the relationship between heavy metal contamination and human health risks using health risk indicators from the USEPA. The study revealed that ingestion risks were higher than skin contact or inhalation, and children were more susceptible to non-carcinogenic threats than adults (Urrutia-Goyes et al., 2017).

In a study in Galway City, Ireland, the use of XRF determined Lead, Copper, Zinc, and Arsenic contamination at a public park, which was previously a garbage disposal site for residential and industrial waste. The heavy metals were found at high concentrations, much greater than the background levels. The study advised immediate soil remediation to prevent children who play there from exposure (Carr et al., 2008).

The soil in an urban residential area in China was evaluated for heavy metal concentrations. The study used XRF to determine levels of heavy metals, and of the 80 samples, 25 were found to have high-risk contamination for lead, copper, zinc, and nickel. The most contaminated samples were closer to roads, which are most exposed to pollution from traffic. The researchers called for stricter zoning regulations to keep residential and recreational areas further from high industrial activities (Liu et al., 2022).

Soil remediation methods include containment, transforming, or removing the contaminated soils, and the distribution of heavy metals in the soil is a significant factor in selecting the appropriate method. In-situ techniques are more efficient because the soil remains in place, while ex-situ remediation, such as excavation and transportation, can be messy and expensive. Encapsulating the area of contamination with concrete or clay is the best choice for small, highly contaminated areas. For a permanent fix, soil flushing involves injecting the soil with an extraction fluid, and chemical immobilization is the best choice for low to moderately contaminated soils. Phytoremediation is a developing method that relies on plants to remove or stabilize metals into harmless forms, and compost application and mulching are low-cost methods for binding and diluting heavy metals in soils (Paltseva et al., 2022).

In conclusion, the potential health risks from exposure to heavy metal contamination in public parks and residential areas is a serious concern. Soil remediation is necessary to prevent exposure to heavy metals, and various methods are available depending on the level of contamination and distribution of heavy metals in the soil. The selection of the appropriate method should consider the budget, time availability, and geographic limitations.

Conclusion

In recent years, concerns about the use of synthetic pesticides and herbicides have led to questioning traditional maintenance methods on public recreational facilities such as golf courses and sports fields. This has posed a challenge for managers to maintain aesthetically pleasing, healthy fields while focusing on human and environmental health. The primary goals of most modern turf management programs are to achieve the expected performance level with minimal input and environmental impact. These principles can be extended to most systems of sustainable management and engineering design for parks, gardens, sports fields, golf courses, and public rights of way.

Managers of park facilities and sports fields at all levels must strive to reduce or eliminate the use of pesticides and synthetic fertilizers on natural turfgrass playing surfaces. However, this poses a challenge to balance acceptable playing surface quality and visual aesthetics with environmental impacts and safety, with the latter being a priority. Unlike home lawns, sports fields, golf courses, and public park thoroughfares present unique problems for functionality, such as higher traffic, larger turf areas, and thus greater environmental impacts. These factors require a greater focus on watershed analysis, drainage, compaction, and runoff before addressing plant selection, fertility, and pest or weed management.

Nutrient management plans and integrated pest management (IPM)-based programs guide the manager to achieve the expected performance level while minimizing pesticide use or excessive use of fertilizer, whether organic or synthetic. Organic management programs aim to achieve the desired performance without adding synthetic fertilizers or pesticides into the system through methods such as organic fertilizers, natural weed suppression, and organic field aeration. Although research in this area is just beginning and sparse, there are many examples in the US and worldwide of pilot programs with eco-friendly alternatives to field maintenance that prioritize sustainability for the future.

Abstract

Traditionally the study of soil has been handled by the natural and applied sciences, and those closely linked to food production or to forestry. Yet new disciplines and sectors of society are increasingly looking towards the soil with the emergence of new concepts being brought to soil science. This chapter provides an overview on how awareness about the importance of soil for civilization has changed over time and describes briefly some emerging topics of soil-society relations beyond the ones traditionally studied. It aims to introduce briefly the chapters in this section, which describe these relationships in more detail.

Key points

- Soil science is an interdisciplinary science.
- Its study does not only incorporate natural sciences, but also increasingly social sciences, the law and art.
- In parallel to the agricultural and environmental sciences and forestry, human and animal health, urban planning and architecture are increasingly demanding knowledge on soil.
- Emerging disciplines such as forensic science need to characterize soil.
- Major societal challenges such as inequality, climate change and antimicrobial resistance, and most Sustainable Development Goals (SDGs) need to include knowledge of the soil.
- Education in interdisciplinary scientific work and in inter-institutional cooperation requires knowledge of the soil and should be fostered to achieve sustainable soil management and reverse soil degradation.

Introduction

The scientific study of soil has focused for centuries on soil formation and on understanding the patterns of soil distribution in landscapes (pedology and soil geography) and in investigating soil functioning, i.e., biological, chemical and physical soil processes. As soil supports crops, land-use systems and agricultural management practices are additional necessary components of an encyclopedia of soil. Land use and management changes in response to shifts in society's demands, require a better understanding of soil-environmental interrelationships and biotechnological advancement. Environmental sciences emerged decades ago and they investigate soil response to climate change and pollution. The respective chapters in the Encyclopedia provide updates on the knowledge acquired in all these areas of soil science. This Encyclopedia of Soils in the Environment includes additional chapters on novel topics in which knowledge has been acquired on many aspects of soil that we might not consider soil science. These chapters highlight how soil is playing an increasingly important role in the 21st century. They show an imaginative and exciting aspect of soil that many will not be familiar with.

Apart from the traditional disciplines involved in the study of soil, many other disciplines, particularly from the social sciences, humanities and arts are increasingly interested in soil. Lawyers develop policies to regulate soil use, to protect it from degradation and to establish rules to rehabilitate the soil when it has been degraded by human mismanagement. Economists value ecological functions to incorporate them into cost-benefit analyses. People working in the health sector need a better understanding of environmental conditions, including those related to the soil because it is now clearly recognized that soil, animal and human health are closely interrelated (Brevik et al., 2020; Gibbs, 2014).

Relatively young disciplines such as forensic sciences often need to include soil characteristics as evidence that links a crime scene to potential suspects. This chapter provides an overview of these emerging soil-society relations.

The chapter further acknowledges the importance of education and outreach to ensure greater understanding of the importance of soil that will help to protect the soil from degradation. Throughout history, urban societies in particular have lost awareness about the importance of soil for their daily lives, but it has never reached the perilous degree of the current century.

The perception of nature and cultural aspects

Soil supports terrestrial life, yet awareness of its importance for daily life is lacking especially in urban societies; it is generally strong within some rural societies that have depended directly on the soil resource for generations. Rural societies until the industrial revolution developed an understanding of soil-plant-water relationships through the close daily contact with soil by growing their food, observing water infiltration and runoff, and disposing their organic residues into soil to maintain its fertility. They gained empirical knowledge which has been passed down for generations. [Homburg et al. \(2023\)](#) document that some civilizations in East Asia or the Andes have developed sustainable management practices in harmony with the environment for centuries and even millennia. In many places population growth, globalization and climate change have led to soil degradation. Their chapter provides examples of the collapse of modern and ancient civilizations based on their access to good quality soil and especially on the knowledge of their members with respect to sustainable land-use practices. Special attention is given to the adaptability of ancient civilizations to climate change, which is not only a current major challenge, but has also been so in the past.

Urban societies are disconnected from the soil as the natural source of food because food is provided by markets, and soil is not considered in relation to potable water, which is brought by pipes through the water supply network, runoff is regulated by the subsurface sewerage system. The nutrient recycling function of soil is further not acknowledged because residues are taken away by the waste collection service. Currently more than half of the world's population lives in cities, however urban societies are often not aware of the importance of soil to sustain terrestrial life. Further, reduced contact with soil does not allow people to engage with soil protection or conservation ([Siebe et al., 2018](#)).

Art can help to foster awareness and communicate the importance of soil for society. The innovative chapter by [Toland and Wolter \(2023\)](#) illustrates how artists are not only considering soil in artistic research, but are also contributing to life-long learning and soil literacy. The different formats of art expression as visual and performing arts, film, literature, music, and various design disciplines address themes that are often beyond those considered by soil scientific investigation. The inclusion of ethical, political and esthetic topics into the overall discourse about soil provides important incentives for inter- and trans-disciplinary research. Art reaches much broader audiences, which in turn helps to promote soil protection in the political agenda. Emotional connections to soil allow people to develop a sense of responsibility to preserve this life sustaining resource. The chapter addresses soil sensitization through soil color, sound, smell, touch and taste; the latter is explained through the concept of 'terroir' which explains subtle taste differences in food or beverages (for example wine) determined by local soil, relief and climate conditions of particular regions.

Education

As stated above, it has become imperative to increase awareness of the importance of soils, and to introduce and enforce soil information in education programs. The chapter by [Reyes-Sánchez and Brevik \(2023\)](#) explores important concepts in soil science education, some of the more common modes of education delivery, groups that soil science educators commonly reach out to, and professional soil science groups that engage in public education. This chapter clearly points out that teaching involves more than just the delivery of discipline-specific content. Active learning approaches (i.e. learning by doing) have proven to be the most effective strategies. Education has to reach all age groups of society, from children to adults, and foster inter- and trans-disciplinary thinking. Different people are increasingly engaging in soil science education, including teachers, members of soil societies and professionals in communication science. Teaching can take place in the formal classroom, in the field, or the laboratory; at the university level, it should also promote academic-industrial partnerships that expose students to complex real-world problems to develop the students' critical thinking skills and expose them to a variety of perspectives. Educating children and teenagers is especially important because their understanding of the value of soil will commit them to its preservation.

Planning and landscaping

The growing world population demands more and more land to satisfy its needs. Land-use systems necessarily have to adapt to the prevailing environmental conditions. Ancient societies designed their land-use systems according to the landscape attributes, potential and environmental conditions, and to their needs (food, clothing, etc.). However, the green revolution of the last century exported and globally distributed technological packages to optimize food production for diets deemed adequate by global health and nutrition organizations ([Denizen, 2023](#)). Current land-use systems have prioritized soil functions related to good extraction over soil functions that regulate and balance the water and nutrient cycles. This has led to the global likelihood that more soil is lost than is formed. In his chapter, Seth Denizen invites change in planning paradigms by incorporating rates of soil formation into the design of land-use systems instead of assessing resource stocks or documenting degradation. Professionals in charge of land-use planning acknowledge just a few attributes that dominantly refer to 'land' characteristics, as dimension, inclination, ownership,

distance to infrastructure, facilities for water supply, exposure to natural hazards, etc. The chapter addresses the problems of including soil as a 'layer' in Geographic Information Systems in land planning, by emphasizing that the often taxonomic legend of soil maps does not allow local cultural, empirical and political aspects to be considered, which strongly affect sustainable land-use practices. Much work needs to be done to foster communication between land planners and local stakeholders, as well as experts in different disciplines such as soil science, economy, politics, etc., to design circular economies centered on building soil resources rather than consuming them (Denizen, 2023).

Law and policy

The jurisdictional perception of soil has changed in recent decades as pieces of land are no longer viewed just as assets owned privately by people, by institutions, or by municipal or state entities who have a right to use and exploit the soil, but is moving towards making land owners responsible to maintain soil ecological functioning. The law and policy aspects involving this new paradigm are analyzed in the chapter by Ginsky (2023). Assurance of global food security, mitigation and adaptation to climate change and the conservation of biodiversity have triggered policy actions to meet the Sustainable Development Goals established by the United Nations General Assembly (United Nations, 2015). Governments are implementing and expanding the legal framework to ensure soil protection and provide incentives for sustainable management practices. International institutions are designing organizational and institutional arrangements to help achieve sustainable soil management. These actions aim to create a system of soil governance, which Ginsky (2023) explains in his chapter. He summarizes the existing regulatory structure internationally and provides some examples of actions taken by local governments. He concludes that containment of soil degradation will be achieved only by strong and effective interinstitutional cooperation.

Forensic soil science is an emerging discipline where soil science is applied in criminal justice systems. It provides soil information and characterization methods to support law enforcement agencies in investigating criminal, environmental, and serious and organized crime. The chapter by Dawson (2023) provides an introduction to this new discipline and explains how information on soil, its minerals, and plant materials helps to determine their provenance and to understand evidence at crime scenes. The soil sampling and characterization methods are carefully adapted to meet the needs of criminal justice systems.

Economy and soil evaluation

Human wellbeing largely relies on goods and services provided by soil. However, soil is a limited resource, particularly when current rates of soil degradation are considered. Many soil ecosystem services are collective goods, which are compromised by mismanagement by the land owners. The preferential use or exploitation of one particular soil function (for example provision of food) often leads to the under-provision of other soil functions (preservation of natural vegetation biodiversity). Public preference for the different soil functions dictates the extent of under-provision of other soil functions and can be estimated by economic nonmarket valuation (Bartkowski and Massenberg, 2023). It has become increasingly necessary to provide incentives to promote sustainable land-use practices and to give economic value to soil services so that they can be considered in decision making. A particular challenge is that many soil services are not traded on international markets and thus do not have a monetary value. The chapter by Bartkowski and Massenberg (2023) provides an economic perspective on soils' contributions to human well-being and indicates potential ways to provide nonmarket valuations of soil services. Policy instruments help to align soil management with public preferences and to optimize soil management to preserve soil multifunctionality. Understanding of the economic effects of soil use and management contributes to effectively and efficiently protecting soils.

Soil and animal and human health

Soil is linked to human and animal health, not only by the nexus soil-food provision and quality, but also because many diseases are transmitted and possibly originated in soil. Polluted soil with potentially toxic elements, radionuclides and organic compounds put human and animal health at risk through the soil-plant-water-air pathways. Soil components such as clay minerals have been used since ancient times to treat skin and stomach ailments. Soil harbors microorganisms such as bacteria and fungi from which many well-known antibiotics have been produced. It is also likely to be a vital source of future ones which is important because of the increase in antibiotic resistance genes. This has been recognized as one of the most important challenges humankind is facing currently, together with global climate change. The chapter by Oliver and Brevik (2023) provides an overview of the different interconnections between soil and human and animal health and emphasizes the opportunities to foster preventative medicine. Awareness about the strong interrelations between environmental, animal and human health is provided by the One Health Initiative (<https://onehealthinitiative.com/>), which also gives incentives to increase interdisciplinary work further on this topic.

Abstract

This chapter presents a sample of a much larger field of artistic research on soils. Alongside advancements in proximal soil sensing technologies, artists contribute new insights on soil sensing by facilitating multisensory experiences, developing new vocabularies for what is sensed, raising awareness about soil ecosystems and their complexities, and producing innovative research on soil phenomenology that can be cited by artists and scientists alike and inspire new interdisciplinary collaborations. Artistic soil sensing, with its diverse foci and forms of presentation and mediation, can target different audiences and segments of society, playing an important role in soil communication, life-long learning and soil literacy-building efforts.

Introduction

The arts, including the visual and performing arts, film, literature, music, and various design disciplines, play a special role in raising awareness about soil protection in that they address a range of different audiences and bring attention to themes of ethical, political and esthetic nature that are often beyond the scope of soil scientific investigation (Feller et al., 2015; Toland et al., 2018). Without claiming the recognition of a new art historical genre, we will use the term “Soil art” in the following to refer to artistic activity with soil materials or in soil environments “that is produced by artists in a multitude of genres and media, to be understood, among other things, as artwork that may contribute to wider environmental and soil protection discourses and awareness-raising efforts” (cf. Feller et al., 2015). Over the past couple of decades, the recognition of artistic works in soil scientific contexts, such as publishing, academic networking, grant consortia, and scientific conferences, and also the role of soil in artistic contexts, such as exhibitions, residencies, performances, and art publications, has evolved from being a marginal interest on both sides to becoming a new frontier for inter- and trans-disciplinary research (First-Arai, 2019; Toland et al., 2018; Adams and Montag, 2016). Collaboration and knowledge transfer across scientific and artistic disciplines has increased since the 2015 UN International Year of Soils, while new forms of communication and public engagement are needed to address soil erosion, soil pollution, soil organic carbon (SOC) loss, soil sealing, and many other “wicked problems”¹ confronting soil health today.

Science communication typically represents a marginal investment in soil scientific research, at least in third party funded fundamental research. Feller et al. (2015) observe that “the last decades show, however, that the activities of the soil science community and its traditional partners have been insufficient in protecting our soils and landscapes.” Soil art is seen as an integral partner in expanding the outreach and knowledge dissemination activities of the soil science community. At least since 2015, raising awareness of soils can no longer be considered a niche interest of soil scientists, but has been “mainstreamed” thanks in part to events such as the 2015 Expo under the motto “Feeding the Planet, Energy for life,” the 2015 UN International Year of Soils and dedicated UN decade of soils 2015–24. Beyond the inclusion of smaller artistic contributions to soil science meetings (e.g., the Soil Cinema and poster exhibition organized by A. Toland at the 20th World Congress of Soil Science in Jeju in 2014 and the Our Living Soils events and exhibitions on occasion of the 22nd WCSS in Glasgow in 2022), several residencies and research groups have recently been developed with a focus on soils, including the Soil Culture residencies in the UK, the Zone2Source residencies in Amstel Park, Amsterdam, Netherlands, Cargo Collective’s Soil LAB in Domaine Départementale de Chamarande, France, Soil Futures at Arts Catalyist in Sheffield, UK, and the Anthropogenic Soils cluster at the Oslo School of Environmental Humanities (OSEH),

¹Design theorists Rittel and Webber (1973) introduced the concept of “wicked problems” to describe complex challenges to society that are symptomatic of other problems and cannot be solved with one approach. The term has been picked up in the environmental humanities and Anthropocene studies in reference to complex problems such as climate change and soil desertification.

Norway. By facilitating relationships and creating identity with specific sites and ecologies, artists have actively contributed to increasing soil awareness and improving soil literacy.

With historical roots in the materiality and visual imagery of landscape painting and the Land Art and Earthworks of the 1960s, 1970s, and 1980s, artists today conceptualize their works on soils and with soil materials, by consciously integrating the historical, cultural, and site-specific dynamics of soils into their compositional, curatorial, material and media choices. Artists have investigated the formal esthetic properties of soils, gaining knowledge on how soil materials react chemically and can be manipulated, e.g., in the kiln, on canvas, or in large scale installations.² Artists explore the embodied, sensory reactions of humans to soils and soil environments in situ or on display, bringing awareness to how knowledge of soil formation is created through sensory experience. Artists regularly engage with landowners and farmers, collecting and integrating their impressions and experiences as primary material to be exhibited to wider audiences (see, e.g., Katie Revell's Farmerama podcasts) or as secondary material in the conceptualization of installations, interventions and more (see, e.g., description of masharu's work below). Soil art, in other words, can be seen as a form of empirical research on soil materials, environments, histories, embodied experiences, and social worlds, mediated through exhibitions, performances, publications, audio, film, and social media formats, and beyond.

While soil art might not seem immediately related to soil science in a strictly disciplinary sense, compared to more established "border disciplines" (c.f. Thompson Klein, 1990, p. 65) such as soil hydrology, geophysics, or agrochemistry, the commonalities between soil science and art are many. Both use keen and systematic observation to derive new understandings of soils; both strive for novel interpretations of nature-based phenomena; both are evaluated based on their creative use of concepts and methods; both are uncertain or risky in their outcomes; both develop processes or products that can be communicated to different target audiences. Indeed these commonalities of "novelty, creativity, uncertainty, systematization, and transferability" represent the main criteria for research itself as outlined in the OECD Frascati Manual—Guidelines for Collecting and Reporting Data on Research and Experimental Development (OECD, 2015 p.28). Positioning soil art as a form of empirical research or artistic knowledge-creation thus goes beyond the recognition of the role of art in raising awareness and facilitating public outreach. Soil art can do more. It mediates soil scientific knowledge to broader audiences, but also generates artistic knowledge and understanding about soils and their central roles in local ecologies and communities. More than simply a mouthpiece for the natural sciences, soil art can be seen as a small but growing field of research-creation in the arts and humanities that expands the scope of soil literacy and enhances the knowledge-base, already well established in the fields of soil physics, soil chemistry, soil biology, and soil taxonomy, and also the applied knowledge held by land managers, foresters, farmers and other practitioners. While a comprehensive overview of soil art is given in the publication *Field to Palette—Dialogues on Soil and Art in the Anthropocene* (Toland et al., 2018), this chapter outlines several key areas of development and draws on several case studies to outline the unique potential of soil art within the soil science community.

The chapter is structured around different approaches to creating sensory experiences with soils, emphasizing how multisensory engagement with soils, can lead to an increased sense of responsibility for soil health, and as an appreciation for the entangled relationships of human societies and the soils that sustain them. Artistic methods are shown to complement the techno-scientific field of proximal soil sensing³ with the aim of making emotional connections between human bodies and soil bodies. On the one hand, they include examples of technologically-conditioned modes of perception through the use of instruments, on the other hand they include direct modes of sensing with the human body.⁴ The idea is that while soil sensing has become essential for monitoring various properties such as soil organic carbon content, erosion rates, and water and nutrient availability, good data do not necessarily lead to good land use practices. Methods of artistic soil sensing can extend the technologically driven "new paradigm for agriculture" (Rossel and Bouma, 2016) by creating sensory experiences that evoke attentiveness and meaningful identifications with place, foster curiosity and wonder, and underline the bodily and emotional connections to soil as a fundamental basis for good practice (cf. Krzywoszynska, 2021).

Soil chromology

Central to discussions on soil sensing is the role of color in the interpretation and use of soils. This has been shown by some of the earliest forms of human communication about their environments in the cave art at Lascaux, France, to contemporary advancements in soil spectroscopy. The range of different approaches to studying soil color and its myriad applications could be subsumed under the term of "soil chromology." Soil scientists Ed Landa (2004) and Fiorenzo Ugolini (2010) provide initial insights on the history, chemistry and meaning of soil color, which is important for many artists interested in soil. The differentiation of soil color has been systematized and standardized over time, most prominently by the painter Albert H. Munsell, whose system for describing soil color is still used today. The Munsell Color System provides "a grammar of color" (Munsell and Cleland, 1921), encoding hue (Hue), gray value (Value), and saturation (Chroma) into numerical values for determining, for example, humus content, oxygen availability, and iron compounds under optimal visual conditions using moist soil samples and direct sunlight at right angles to the

²See, respectively, the works of glass artist Sarah Hirneisen, painter Ulrike Arnold, and conceptual artist Lara Almarcegui in *Field to Palette: Dialogues on Soil and Art in the Anthropocene* (Toland et al., 2018).

³Proximal soil sensing (PSS) refers to electrochemical, spectroscopic, geophysical and mechanical sensing methods used to gather data on multiple scales for scientific study, soil mapping, and land management recommendations. See Adamchuk et al. (2015) for a comprehensive overview.

⁴See Schneider & Zemanek, 2020, and Gabrys, 2016, for critical discussions on environmental sensing technologies.

color chart. Contemporary artists have often turned to Munsell color charts in their public engagement with soils, but go beyond Munsell's system to create their own taxonomies of soil color using artistic means. As has been described in Toland and Wessolek (2014) and Feller et al. (2015), bringing attention to the diversity of soil color is a common thread in artistic work with soils. This is especially evident in the works of Ellie Irons' participatory cartographic work in Philadelphia and New York; Peter Ward's collection of earth pigments in former mining areas in western England (eARTh—An Exploration of Earth Pigments in North Devon, 2008–18); Elvira Wersche's elaborate geometric floor installations using different colored sands from around the world; Ulrike Arnold's abstract in situ paintings using local soil samples; environmental art pioneer Herman de Vries' collection of boxed soil samples and soil rubbings from around the world organized as a soil archive; Koichi Kurita's grid installations and glass bottles of sifted soil samples from over 30,000 communities in Japan; Margaret Boozer's installation "Five Borough Reconnaissance Soil Survey" spatial interpretation of the New York Soil Survey; the Soil Alliance of Lower Austria's outreach project with Irena Racek, and the "One Earth Altar" collection of soil books started by Marianne Greve for Expo2000 in a church in Schneverdingen, Germany. Despite different compositional, material, and presentation format choices and exhibition outcomes, all these works bring attention to the enormous diversity of soil color that is usually hidden beneath our feet. The collections of soil samples in these artworks are archives of soil diversity, that despite having been moved from places of origin, create an awareness for soil as more than a homogenous brown substrate in which to grow crops. Artists shine light on a veritable subterranean rainbow of difference usually inaccessible to human vision.

In addition to these and other artistic approaches to communicating soil diversity through the archiving and presentation of large amounts of soil samples, color also plays a role in the assessment of sites and narration of their histories, vulnerabilities and potentials. Recent observations of soil art projects at exhibitions, festivals, and residencies include the renaissance of soil chromatography as a qualitative, visual method for site assessment, as well as the development of new tools for color-coding soil properties, both with the assumption that color can communicate snapshots of soil health at particular sites. Developed in the 1950s by Erenfried Pfeiffer, an associate of Rudolf Steiner, soil chromatography has been promoted in biodynamic farming circles as an easy and inexpensive method for visually analyzing the organic content, mineral make up and microbiological activity of a given soil (Pfeiffer, 1984). To make a soil chromatogram, a soil sample is first mixed with a dilute solution of sodium hydroxide to gently break down the mineral and organic components of the soil. The mixture is then applied to a round filter paper treated with silver nitrate by pouring the sample into a petri dish and allowing it to enter the middle of the filter paper through the capillary action of a wick inserted in the center of the paper. A unique radial image consisting of channels and spikes emerges as the different components are soaked up by the paper at different rates. Over the past several years the technique has been embraced and popularized by artists and artist groups such as Debra Solomon (Fig. 1), Claire Pentecost and Brian Holmes, Julien Chollet and mikrobiomik (various workshops, ongoing), Aino Johansson and Sirja Moberg, Hannah Fletcher, Scott Hunter (ongoing), Phil Lambert and others.

The reliability of soil chromatography for soil health assessment has been questioned by scientists such as Ford et al. (2021) who carried out extensive testing of the method and concluded that only weak correlations between chromatographic readings and soil variables could be found, however, the esthetic potential of the method should not be underestimated. What is unique about soil chromatography is its reliability and replicability as an artistic means of public engagement with soils in diverse settings. It is important to note that the artists mentioned above have usually produced soil chromatograms in workshop settings, field trips, and other participatory settings, facilitating hands-on experiences and in-depth exchanges about soil health, often with people who are not professionally connected to soils. Soil chromatography offers a way of creating colorful holistic portraits of local soils that

become objects of contemplation, conversation and wonder, and ideally an increased feeling of responsibility for soil health in gardens and farms, urban spaces and backyards, and beyond. For artists, it is not the accurate correlation between soil properties with the radial patterns on the filter paper that determines the reliability of soil chromatography as a method, but rather the continued interest of art spaces and their audiences with this specific means of soil portraiture and its potential for connecting people to local ecologies.

Beyond work with soil pigments and soil chromatography, another group of artists and designers are using color to code various soil properties to make field data more user-friendly. Under the direction of bioart pioneer Suzanne Anker, a mixed group of art and science students took part in the prestigious iGEM (International Genetic Engineered Machine) competition in 2015 with the project “Soiled,” which won a gold medal for Best Art and Design Project. Informed by developments in soil spectroscopy, Soiled applies color as a metric for analysis. Using a spectrophotometer, an assigned wavelength of light was beamed through a soil solution to measure how much light was absorbed. The team developed a microfluidic chip that assigned quantitative values to color dots, resulting in a color map (Fig. 2) visualizing the available nutrients of soils sampled from over 50 locations in New York City. What is notable about Soiled is that it shows how artists can develop and are interested in developing quantitative methods for depicting soil diversity, and that soil art can capture not only individual portraits of soils but can be used as a reliable (and beautiful) tool for visualizing their bio-chemical characteristics. Albert Munsell’s gift to the soil science community was a hands-on, systematic tool for visually assessing mineral composition, humus content, and soil processes such as carbonate accumulation, among other things. It is only natural to expect that artists will contribute to soil sensing methods of the future.

Sounding soil

While the above projects use visual methods for capturing impressions and information about soil, we might next ask: what does soil sound like, and more importantly how could listening to soils improve our understanding of soil ecosystems? This question has led to fascinating research and development in both the sciences and the arts. Although Liu et al. (1993) had started testing acoustic methods for determining soil texture in the early 1990s, Tekeste et al. (2002) have since used sound waves to detect compacted layers, Koparde et al. (2018) have used echo signal processing in soil base profiling and sub-bottom profiling, and O’Shaughnessy and Sui (2018) have introduced radio frequency (RF) telemetry to precision agriculture. Worthy of mention on the artistic side are Florian Dombois’ (1999)⁵ “earthquake sounds,” Shu Lea Cheang and Martin Howse’s (2013)⁶ use of sensors to sonify rotting vegetables in “Composting the City/Composting the Net” (see also Howse’s “earthboot” and other noise works), Daniel Wolter’s

(2019-2023) audio-visual analysis of different landscape types in the Biosphere Reservation Chorin, and Olle Corneer and Martin Lübke's (2009)⁷ "Harvest Terrafon," in which the Alunda Choir of Uppsala, Sweden, pulled an oversized gramophone through grooves in a field to amplify cropland soils.

Marcus Maeder et al.'s case study at the interface of artistic research, acoustic ecology and soil science, "Sounding Soil," represents one of the world's first studies dedicated to the acoustic phenomenology of soils. From 2017 to 2020 Maeder led a 20-member team as part of a research consortium between the Zurich University of the Arts ZHdK (Institute for Computer Music and Sound Technology), the Swiss Federal Institute for Forest, Snow and Agriculture Research (WSL), the Swiss Federal Institute of Technology Zurich (ETH), the National Soil Monitoring Office (NABO), and the Biovision Foundation for Ecological Development to develop methods for acoustic analysis of biological activity in topsoils. In 2017, 20 test sites were selected based on land use type and humus types present. For the recordings, sensors from the field of physical acoustics, including piezoelectric sensors, were modified for use in soils.⁸ Using piezoelectric sensors, vibrations were converted into electrical voltage, which in turn was amplified and captured as sound signals by a recording device. The recordings were made with probes about 30-cm deep and 60 cm in diameter, representing the area of the soil profile with the most biological activity. In addition, soils samples at the recording sites were taken with a puncture cylinder (Kempson corer, 30 cm ø, 20 cm length) and analyzed in the laboratory. Using the Berlese and Winkler method, soil fauna were extracted from the sample material and identified taxonomically and counted (cf. Maeder et al., 2019).

In October 2018 an immersive installation was opened at the Paul Klee Centre in Bern, consisting of a converted shipping container with a green roof and dimly lit listening room (Fig. 3). Small tubes for air and light in the ceiling represented macropores in the soil matrix. Sounds of the soil recordings included clicking and tapping sounds, vibrations, hissing, sighing and a variety of mechanical scratching movements. The muted walls of the structure created the impression of depth and seclusion reminiscent of the feeling of diving underwater. Surges of activity and intensity of audible phenomena in the recordings drew attention to the different soil factors in different locations. Weather and above-ground atmospheric sounds were added to create holistic "soundscapes" of the soils sampled.⁹ The term soundscapes, first introduced by R. Murray Schafer in 1977, refers to, "...any acoustic field of study. We may speak of a musical composition as a soundscape, or a radio program as a soundscape or an acoustic environment as a soundscape. We can isolate an acoustic environment as a field of study just as we can study the characteristics of a

given landscape” Sterne (2012). Like other acoustic engagements with soils, Maeder’s project encourages visitors to think differently about the local soundscapes that surround them and to imagine how the soil in their own backyard might compare acoustically to that in a field, a forest, or a construction site.

Beyond the esthetic qualities of Maeder’s soundscapes, the Sounding Soil study has relevance for soil health research. Biological activity is a key indicator of soil ecosystem functionality, especially in the assessment of soil biodiversity (see Wagg et al. (2014)). Sounding Soil investigates the complexity of soil soundscapes, asking whether the degree of land use, as well as humus composition, influence complexity values. Acoustic complexity plays an important role in ecoacoustic research because it can be used as an indicator of biodiversity for a particular unit of the landscape (see Pieretti et al., 2011). Within a soundscape, the diversity and complexity of sound data are measurable quantities. The acoustic complexity index (ACI) was used to quantify the acoustic complexity of soil organisms directly without including anthropogenic sound sources, which are commonly found in recordings (cf. Pieretti et al., 2011). Furthermore, significant differences in acoustic complexity were found between different land use types, with the greatest complexity for extensively managed pastures and the least for cropland soils. Forest soils and intensively managed pastures were in the middle range. The analysis further showed a weak positive correlation between the values of acoustic complexity and those of biological diversity of higher groups of soil organisms analyzed in the laboratory. For cropland and pasture soils, increased diversity of soil fauna correlated with decreasing management intensity, which in turn resulted in greater acoustic complexity. Among forest soils, there was a correspondence of curves between ACI measurements and the respective humus forms as habitat for soil fauna, with a gradual increase from mor humus to mull humus (cf. Maeder et al., 2019). Following developments in proximal soil sensing, acoustic analytical approaches can be considered a cost-effective alternative to more conventional forms of field measurement and laboratory analysis, in which disturbance to the soil matrix is reduced. Sounding Soil demonstrates that artistic research can serve as both as a tool for analyzing soil ecological properties and a means of facilitating sensory esthetic experience and raising awareness about the complexity of life underground.

Soil scenting

In her essay “The Aesthetics of Smells and Tastes,” philosopher Emily Brady (2005, p. 177) emphasizes the fundamental role of the so-called lower senses in appreciating one’s surroundings: “Sniffing and savoring not only form a fundamental pathway to sensory perception of our environment, but they also help define the quality and character of people, places, and events.” For soils, one of the most common associations and direct forms of esthetic appreciation is smelling and tasting, for example, in growing, preparing, and eating food grown in soil. In an attempt to evoke olfactory connections between soil and place, designer and food systems planner Lynn Peemoeller created a series of artisanal soil scents arranged on a product stand she designed for the international stakeholder conference “Global Soil Week” in 2013 in Berlin. Between plenary sessions on soil policy and sustainable development, conference guests were able to pause their agendas to tune into their own physical experiences with soils. For 5 days, Peemoeller handed out perfume samples of Tegel Forest soils, compost from a nearby community garden, and an ambiguous cocktail of street residue collected from Potsdamer Platz (all locations in Berlin), evoking powerful associations and memories by activating olfactory experience in the most unlikely of places. Peemoeller’s soil scent stand stood out against the typical conference venue tables with pamphlets and soil society merchandise, with the provocative question: what does soil health smell like?

The extraction of soil for use in perfumes has a long history, originating in the town of Kannauj, the so-called “perfume capital” of India, in the north-central rural state of Uttar Pradesh. In the book, *Rain: A Natural and Cultural History*, Cynthia Barnett (2016) tells the story of Australian mineralogists Isabel Joy Bear and Richard Grenfell Thomas, who published an article in the journal *Nature* in 1964 identifying the smell of fresh rain on the ground as coming from plant compounds called terpenes that were absorbed by clay soils. They called the smell “petrichor,” although it already had a name in Hindi—mitti attar, or earth perfume (Barnett, 2016). Today, one of the most popular commercially available earth perfumes is also called Petrichor. Distilled by the U.S.-based Demeter Fragrance Library, Petrichor similarly evokes the scent of soil after rain. Following the work of Bear and Thomas, a group of chemists at Brown University were able to identify the enzyme responsible for the smell of Petrichor as geosmin (see Jiaoyang et al., 2006). The presence of geosmin, literally “the smell of the earth,” is also a criterion for soil quality checklists.¹⁰ Olfactory descriptions for the screening include impressions such as sweet, foul, pleasant or unpleasant, musty, acrid, or soothing smells of soils.

Perfumers and other olfactory artists like Sissel Tolaas, Kate McLean, Lynn Peemoeller and others could help soil scientists, land managers, and the general public sharpen their vocabulary of soil odors by conveying abstract associations of combinations of mineral and organic compositions. While compounds such as alcohols, ketones, nitrogen-containing compounds, resins, tannins, etc., can be measured with gas sensors,¹¹ verbal associations remain beyond the realm of numerical data collection. Smells are experienced as olfactory sensations that directly inform the body about the health or hazard of soils. They form the foundation of what Porteous (1985) termed the “Smellscape,” or the cognitive ordering of spatial units based on particular smells or combinations thereof. The development of a soil smell vocabulary was the focus of Petrichor, a multi-part, multi-disciplinary science-art research project by artist Anaïs Tondeur in collaboration with anthropologists Marine Legrand and Germain Meulemans, ecologist Alan Vergnes, designer Yesenia Thibault-Picazo, and curator Nathalie Blanc. The team came together as part of the Sustainable

¹⁰See, for example, the Illinois Soil Quality Initiative (ISQI) for agricultural soil screening tests, which include smells as indicators.

¹¹See, e.g., recent research on artificial olfactory systems (AOS) by Zhu et al., 2019.

Cultures Laboratory, initiated by COAL and the Domaine départemental de Chamarande during the 2015 International Year of Soils and continued with further iterations through 2018. Inspired by the work of Bear and Thomas, described above, the Petrichor group sampled soils at urban sites in Paris, Montpellier, and Aberdeen, in an attempt to develop an olfactory soil classification as envisioned by Parisian chemists in the 19th century.¹² Using methods of speculative fiction and anthropological fieldwork, the project invited participants, including gardeners, refugees, activists, graduate students, and elementary school students, to reflect on life in the city and the body's inherent connection to soil, even in predominantly sealed places where it is less visible. The results of the fieldwork were presented as an immersive installation (Fig. 4) of soil distillates, distillation apparatuses, and photographs and videos of soil sampling. As with Peemoeller's soil perfumes, Petrichor uses distinctive smells to evoke associative responses toward the development of a new vocabulary for soil smellscape. Analogous to work being done with soil color and color instrumentation design for soil analysis, olfactory artists demonstrate ways of assessing soil materials and sites that go beyond soil health checklists and proximal soil sensing to create sensory experiences with soils that evoke emotional responses and associative language. The description of the smell of a parking lot or forest after rainfall evokes an entirely different emotional response from a graph showing geosmin levels in the gases emitted from the same parking lot or forest.

Terroir

In Laura Parker's project, *"Taste of Place,"* a table is set and the California-based artist pours clumps of soil into wine glasses. She then activates olfactory experience by adding water and vigorously mixing. Guests spend time smelling, reflecting, remembering, smelling again, then trying to put their experience into words. "Salty, silty, mineral, wet, earthy, and green were just a few of the adjectives we threw out," writes Anne Zimmerman (2009), blogger for Cullinate, "all seemed like logical descriptors for soil." After sharing tasting notes, guests are served with vegetables, cheeses and eggs grown on the different soils in the wine glasses. As the event progresses, sensory connections are made between food and the soils they come from: a childhood memory of eating potatoes or

¹²See project description online: <https://anaistondeur.com/petrichor>. Accessed Oct. 10, 2022.

carrots from a grandparent's garden, the mouthwatering feeling of sauerkraut or kimchi made from a neighbor's cabbage. Parker's work trains guests to recognize and articulate "terroir" or the subtle differences in taste influenced by local conditions, such as soils, topographical relief, and the climate of a particular region.

Making connections between soil and food is a central strategy of many artists working with soils. Toland et al. (2018) initiated dialogues between artists and scientists who focus on food production and terroir in their work, including: a discussion between eco-art pioneer Agnes Denes' and former IUSS president Rattan Lal on the role of urban agriculture in food security and world peace; an exchange between soil scientist Brent Clothier and fourth generation farmer and artist Matthew Moore about terroir as a means of communicating the productive capacity of soils; social scientist Parto Tehrani-Krönner's ideas about "Meal Culture" as an alternative concept to food security; Roxanne Swentzell's experimental use of permaculture to promote indigenous diets; and introspection on soil pollution and community health brought to light in conversations between Bonita Ely and Richard MacEwen, and Amy Franceschini and Regine Debatty. Like Parker's Taste of Place, the works discussed were often created in participatory settings that invited reflection through sensory experience.

While these and other artists highlight the connection between food and soils in their work, the concept of terroir rarely refers to the eating of soil itself. Geophagy, or the desire to eat soil, offers a unique perspective on the sensory experience of tasting soil. In this respect, the work of Amsterdam-based artist masharu is worthy of note. Masharu's extensive artistic explorations of geophagy offer inspiring insight into the historical, culinary, and medical practices that have all but disappeared from Western cultures (Fig. 5).¹³ Drawing on their own childhood experiences of eating soil, masharu became interested in geophagic practices after moving to the Netherlands from Russia. In Amsterdam, masharu encountered clays and chalks from Tanzania, Nigeria, Ghana, and Suriname, among other places, and began interviewing clay traders and tracing the origins of edible soils. Limiting the palette to mineral samples and avoiding fresh organic topsoils for health reasons, masharu uses a variety of forms and formats to share their enthusiasm and knowledge about geophagy. These include a video archive and interactive website that describe different cultural practices of eating soil, tasting workshops, and an installation of variable dimensions for the growing collection. As part of the Edible Earth Museum, masharu has built an archive and database of more than 200 soil samples from 24 countries, acquired as gifts and on field trips, from online sources, and from health and specialty stores.

Anthropologist Sera Young (2012) has documented historical, ethnographic, and biomedical findings on picacism, the consumption of non-food artifacts including soil. While eating clay is considered unhealthy and even psychologically pathological in most of Europe and North America, it is still widely practiced by traditional healers in Africa and South America. In an interdisciplinary workshop in 2018, Young joined masharu and other artists, health researchers, geologists, and food safety experts to discuss the paradox of clay consumption as a healing and even medical act, and the taboo of pica as a psychological disorder.¹⁴ For masharu, anthropological questions about how and why people eat soil are central to their participatory investigations: it is important not only to create taste experiences, but also to understand the individual histories, memories, and cultural contexts of clay consumption.

For the project Claynialism in 2015 masharu collaborated with Arie Syarifuddin from the Jawa Barat (Indonesia) based, Jatiwangi Art Factory and the ceramist Lonny van Ryswyck, from Atelier NL (Netherlands).¹⁵ Together, they explored issues of food colonialism and searched for traces of geophagy in former Dutch colonies and also in contemporary cities in the Netherlands.

In a paper for the performance symposium Unknown Grounds, Masharu (2019, p. 31) asks: “What is behind the traditions of eating the earth? (...) How do the material properties of the earth influence taste?” Following the formal language and fascination about terroir described above, masharu and their colleagues collected mineral samples from the Netherlands, developed regional tasting notes, and conducted chemical analyses, which were in turn documented in interactive installations that ask visitors to consider the western suppression of geophagy as a cultural practice. In some iterations of the project, mineral soils from masharu’s archive were pressed into edible bars reminiscent of chocolate. On other occasions, wafer-thin clay tea cups could be eaten or filled with other edibles to create flavor combinations. At the “Our Living Soils” exhibition at Zone2Source Amsterdam, the artist passed out Stroopwafel with Luvos clay inside. In all presentation formats and exhibition sites, two elements of the work are central: edible clays and people coming together to taste them. Again, the participatory nature of the work stands out as a salient feature of artistic soil sensing. It is not soil sensing alone that constitutes the art, but rather the collective experience of interacting meaningfully with soils in diverse groups that are often distanced from soils.

Multisensory absorption

The projects described thus far have been singled out for their attention to particular senses. The complexity of soils, however, demands a multisensory sensibility to fully appreciate the soil ecosystems from which individual projects are developed. The ocular experience of perceiving color or acoustic experience of listening to a soundscape is inextricably linked to the sense of touch, smell, taste, temperature, gravity and magnetism. Early soil science terminology once recognized the sensory properties in naming soil types, such as terra rossa (Italian for red soil) or rendzina (Polish word describing a sound made by a plow hitting rocks). Soil art provides esthetic means for a “sensorial turn” in the soil sciences, analogous to proximal soil sensing (cf. Stein et al., 2004). The last case study we would like to present is a work that embraces the multisensorial reality of soil, which is also inherently social, in that sensory awareness can be shared, taught, and learned.

“Absorption” is generally known as the process by which one material (the sorbent) takes up and retains another material (the sorbate).¹⁶ In soil scientific contexts this amounts to the water holding capacity of the soil, which depends on a soil’s textural qualities, organic matter content, and topographical position in the landscape. Interpreted through artistic means, absorption can be understood as the experience of stimuli being fully taken up by all the senses—to become absorbed. The room installation, “Absorption,” by the Berlin- and New York-based artist Asad Raza is an invitation to become absorbed by the smell, feel, sound and sight of soil. Although the work has been exhibited in multiple locations, including Carriageworks, Sydney (2019), the “Down to Earth,” (Fig. 6) exhibition at Gropius Bau Berlin (2020), the Ruhr Triennial in Essen (2021) and most recently at the “We are Compost/Composting the We” exhibition at the Centre of Contemporary Art Glasgow (2022), Absorption is reconstructed under similar conditions each time with reproducible reliability. Despite local variability, Raza’s (2019) methods are clearly outlined: (1) recruit a coordinator, scientific advisors, and cultivators who will identify and gather local waste products and natural

Fig. 6 Asad Raza, Absorption, 2020. Cultivator tilling the “neosoil” for the exhibition “Down to Earth” at Martin Gropius ‘Bau, Berlin. Photo: A. Toland. Reprinted with permission by the artist.

¹⁶<https://www.encyclopedia.com/science-and-technology/physics/physics/absorption>

ingredients for the creation of a “neosoil” that is to be mixed together (e.g., using cement mixers) in order to fill an entire gallery space; (2) create engagement with visitors through regular tilling and measuring of the neosoil by hired cultivators who interact with visitors when they show interest in the work, answer questions, ask questions, and offer empty cloth bags to be filled and taken home; (3) give away all leftover neosoil to local allotment gardens and members of the community at the end of the exhibition.

Raza’s work makes reference to Walter de Maria’s iconic “Earth Room,” which was similarly exhibited in multiple locations and confronted visitors with a room full of earth-like substrates to be absorbed by multiple senses. The only remaining Earth Room, consisting of a meter-thick layer of soil was installed by de Maria in 1977 in a loft at 141 Wooster Street, NYC, and has been watered and weeded for over 40 years by DIA Art Foundation staff member Bill Dillworth. Dillworth’s maintenance of the Earth Room happens during off hours to allow visitors to experience the work without interruption. In addition to referencing de Maria’s use of minimalism to create or affect, “Absorption” also references “relational art,” described by Bourriaud (1998) as “art taking as its theoretical horizon the realm of human interactions and its social context, rather than the assertion of an independent and private symbolic space.” The point of “Absorption” is not only to have a multisensory experience, but to anchor that experience in the relationships with diverse materials and to those who care and cultivate them. The cultivators in this sense have been selected from a large pool of applicants and have gone through intense training that teaches them on the one hand how to measure soil conditions and on the other, how to read and communicate with an audience.

Touching or walking on the soil of de Maria’s Earth Room remains outside the boundaries of the artwork, which can only be viewed through a small doorway shielded by glass. While the Earth Room encourages contemplation of soil as an omnipresent natural material in juxtaposition to the sealed city streets outside the gallery, Raza explicitly invites visitors to touch and literally become “absorbed” with soils directly sourced from the city outside. These include, for example, in the Glasgow iteration: washed fine-grained building sand, dredged silt from Scottish canals, red terracotta grogged marl, crushed rubble, crushed oyster shells (formerly used as building mortar), spent hops and barley from local breweries, coffee grounds and cocoa husks, hair from the local barber, vegetable waste from local restaurants, and peat-free compost from the municipality. Compared to de Maria’s ubiquitous “Earth” of unknown (presumably agricultural) origin and composition, the materials in “Absorption” reflect the unique economic and political history of the city, listed clearly on a poster leading into the room and explained by the cultivators.

Coming in from the street, one steps onto the soft and uneven ground, comparable to that of a freshly plowed field. The acoustic environment overwhelms the body in muted silence broken up only by the sound of rhythmic raking while the air is heavy with a smell reminiscent of burning chocolate and rainfall. A trained cultivator explains that she is digging freshly discarded cacao waste from a local roastery into the substrate. Its composition represents an ideal-typical soil of 30% sand, 30% silt, 30% clay and 10% organic matter and calcareous materials. A collection of tools and instructions typically used in field work and soil mapping introduces visitors to basic instruments of soil assessment. After systematically folding in new materials with spades, cultivators rake and spray the surface and explain how to take pH measurements, use Munsell charts to determine organic content via color codes, and perform finger tests to train visitors how to recognize soil textures. The artwork uses the same techniques for assessment in the forest or field to assess the health of the neosoil “as neologism”. A group of soil scientists visiting the exhibition in Glasgow on occasion of the 22nd World Congress of Soil Science debate whether “Absorption” is a room full of amendments, a technogenic substrate, or a constructed soil, generating interest not only from general audiences, but inviting reflection on the meaning and origin of technical terms sometimes taken for granted by experts.

In reference to Latour’s (2015) Gaia Lectures, published during the International 2015 Year of Soils, “Absorption” is finally a critical examination of human presence in the planet’s “critical zone” and in the pedosphere in particular, as well as the presence of soil in human zones. Before visitors leave the exhibition, they are encouraged by cultivators to put some neosoil into bags to take home and further cultivate. In this way, visitors are not only given a gift of (portable) sensory experience, but they are expected to appropriate the artwork themselves by relocating materials that have already been relocated and caring for something that has already been cared for. Challenging standard definitions of soil, which require an extended period of place-based weathering and evidence of soil formation, Raza’s neosoil implies a definition that accepts displacement as a condition of the Anthropocene but also considers care as a necessary criterion for soil being soil. Degraded, carbon depleted soil loses its status of soil and becomes “dirt” in the absence of care. As a work of social sculpture, Absorption empowers visitors to “care forward” and take greater responsibility for soils, starting with one bag. It is in their hands from that moment on to find a place for soil in their lives. The small print at the bottom of the cloth bags reads: “composed of animate stardust, congregated here, absorbed in this.”

Conclusions and outlook

This chapter presents a representative sampling of a much larger field of artistic research on soils. As an overview, it by no means claims to be exhaustive. Together with advancements in proximal soil sensing technologies, artists contribute new insights on soil sensing by facilitating multisensory experiences, developing new vocabularies for what is sensed, raising awareness about soil ecosystems and their complexities, and producing innovative research on soil phenomenology that can be cited by artists and scientists alike and inspire new interdisciplinary collaborations. Artistic soil sensing, with its diverse formats, foci, and forms of presentation and mediation, can target different audiences and segments of society, playing an important role in soil communication, life-long learning and soil literacy-building efforts. Given the long history of sense-based measurement in soil science, from the use of finger tests and Munsell color charts to body-extending sensing technologies to gather soil data at different spatial and temporal scales, soils offer fertile ground for exploring human understanding of sensory perception itself. Artistic soil sensing is thus

not only a relevant area of research and development for soil systems science and the arts, but also for the fields of sensory studies, media anthropology and phenomenology. Beyond the five Aristotelian senses, it is worthwhile to consider the ways soil organisms rely on a host of additional senses such as temperature, gravity, balance, and magnetism, among others to navigate life in the pedosphere. Extending the realm of soil sensing not only to new technologies but also to other non-human organisms provides a multispecies context for further research on the subject.

What is only briefly touched upon in this chapter and urgently needs attention is the potential of artistic soil sensing in contexts of environmental justice, food sovereignty and seed saving, rights to nature, and indigenous soil management and land-back movements. Howes and Classen (2014), among other scholars of sensory studies, have emphasized the need for understanding sensory stimuli in social contexts. For the 2022 exhibition “We are compost/Composting the We at the Center for Contemporary Art Glasgow,” Désirée Coral makes reference to gustatory experience with heirloom seeds from the Americas and copper spoons that throw shadows in the shape of South American countries in “Eating the Ancestors.” Compared to some of the extensive earth pigment collections mentioned earlier, the display of soil-filled jars in the “Memorial to Peace and Justice” exhibition in Montgomery, Alabama has a haunting effect in the realization that the colorful, neatly ordered soil samples are gathered from selected sites of over 4000 documented terror-lynchings of African Americans in the United States. Meanwhile, the multisensory esthetics of Walter de Maria’s “Earth Room” are recontextualized in the earthworks of Delcy Morelos, who pays tribute to Andean and Amerindian cosmologies through the composting of aromas from cassava flour, cacao powder, and spices from the artists native to Columbia into large scale displays of soil materials. Otobong Nkanga’s “There’s No Such Thing as Solid Ground” (2020, Martin Gropius Bau Berlin) similarly uses a multisensory approach to explore the tensions between extractive relationships and practices of care and repair. These and other artists create sensory experiences to highlight the social and political entanglements of soils as historical archives with witnessing and storytelling capacities, and to frame soils as effective media for healing and reparation. Given the violent history of colonial land take, displacement of agricultural communities, destruction of prairies, forests, and wetlands for highest economic gain, and the erasure of indigenous land use practices, knowledge and technologies, both the sciences and arts are called upon to reflect, repair and decolonize. Artists can show that raising awareness about soils is not only about facilitating sensory experience and esthetic appreciation in and of itself but can offer space for critical reflection on the consequences of extractive capitalism and colonialism, and the roles of science in the past, present and future of soil cultivation. Beyond the display of color and texture, taste, smell, and sound, Soil art can do more.

Abstract

Forensic soil science is the application of soil science in the context of the law. Soil materials can be used in forensic investigations to evaluate potential associations to support law enforcement agencies in investigating criminal, environmental, and serious and organized crime. Soil recovered from a questioned item, with an unknown history can be compared with known locations such as crime scenes and alibi locations. Forensic soil science is used to assist in search operations where soil can help narrow down areas to focus the ground search activities (provenancing) and as trace comparison and evidence in court. Established concepts, standardized approaches and professionalism have been developed in soil science and should be carefully applied regarding the legal context to allow the appropriate and safe application of soil science within the criminal justice systems worldwide.

Glossary

ENFSI APST The Animal Plant and Soil Traces expert working group (APST) supports the aims and objectives of the European Network of Forensic Science Institutes (ENFSI) in the area of casework analysis of all kinds of biological traces of non-human origin and soil traces.

FTIR Fourier transform infrared (FTIR) spectroscopy is an established analytical tool for studying soil. The sensitivity of FTIR spectroscopy to local structural environments of infrared active soil components offers a multitude of applications that complement conventional soil science analytical techniques.

GIS A geographic information system (GIS) is a type of database containing geographic data (that is, descriptions of phenomena for which location is relevant), combined with software tools for managing, analyzing, and visualizing those data.

IR Infrared spectroscopy (IR spectroscopy or vibrational spectroscopy) is the measurement of the interaction of infrared radiation with matter by absorption, emission, or reflection. It is used to study and identify chemical substances or functional groups in solid, liquid, or gaseous forms.

IUGS IFG The International Union of Geological Sciences (IUGS) Initiative on Forensic Geology (IFG) was established at UNESCO headquarters in Paris, France on 22 February 2011. The aim of the IUGS-IFG is to develop forensic geology internationally and promote its applications.

Pedology (From the Greek *pedon* = soil) Is the soil science discipline concerned primarily with understanding the variety of soils and their distribution and is most directly concerned with the key questions concerning sampling, descriptions, processes of soil formation including the quality, extent, distribution, spatial variability, and interpretation of soils from microscopic to megascopic scales. This description and interpretation of soils can be used in addressing the questions 'What is the soil like?' and 'Where does it come from?' (i.e., provenance determination) in studies relating to characterizing and locating the sources of soils to make forensic comparisons.

Provenancing Provenancing is the capability to spatially constrain the likely region of origin of a questioned sample of earth-related material.

Questioned sample A questioned sample is a sample with unknown origin, often recovered from a suspect or an item associated with a suspect.

SEM Scanning electron microscopy is a type of electron microscopy that produces images by rastering a focused electron beam across the surface of a sample. This technique produces detailed images of a specimen's surface. Its applications include surface topography and spatially resolved elemental composition using Energy Dispersive Spectroscopy (EDS) or Energy Dispersive X-ray Spectroscopy Analysis (EDXA). SEM produces images up to a magnification of 500,000 $\times$ and a typical resolution power of a few nanometers.

Wax markers The cuticular wax compounds found in plant leaves, which slowly decompose and break down in soil, leave behind a distinctive profile reflecting the history of plant inputs to the soil. The most common and widely studied wax-marker compound class is the hydrocarbons, including *n*-alkanes, and the free and esterified long-chain fatty alcohols (high molecular-weight, straight-chain primary alcohols, derived from natural fats and oils) and fatty acids (carboxylic acids with a long aliphatic chain, containing a hydrocarbon chain and a terminal carboxyl group).

XRD X-Ray Diffraction or XRD, is a technique for analyzing the atomic or molecular structure of materials. It is non-destructive, and works most effectively with materials that are, or part, crystalline.

Key points

- Forensic soil science is the application of soil science in the context of the law.
- Forensic soil science can provide data (intelligence) to assist in search operations where soil, minerals and botanical information can help narrow down geographical areas to focus the ground search activities (provenancing).
- Soil recovered from questioned items, with an unknown (questioned) history, such as vehicles, clothing, and tools, can be compared with specific known locations such as a crime scene (trace evidence).
- Soil forensic characterization involves a staged strategic approach; first with visual examination of physical characteristics of soil (color, texture and morphology) then chemical, physical and or biological analyzes.
- Established concepts, standardized approaches and professionalism have been developed in soil science and are carefully applied to allow the appropriate and safe application of soil science within the criminal justice systems.
- Effective communication is vitally important, from the initial discussion with the investigating officer to the presentation of evidence in court.

Introduction

Forensic soil science is the science of the application of soil information to help answer legal questions, problems, or test related scenarios or hypotheses and to help provide evidence in a court of law. Soil is composed of a range of different-sized mineral particles (described as sand, silt, and clay), the inorganic components, and the organic matter components (often described by its individual organic compounds). Soil has many complex biological, chemical, physical, mineralogical, organic, and hydrological properties, which change through space (horizontally and vertically down a soil profile) and through time (soil can take thousands to millions of years to form and minutes to be lost). Soil is found across most of our terrestrial world and can be both natural and human made. Natural soils contain natural minerals and natural organic materials, which in natural soils reflect the underlying geological parent material, as well as the land use, climate, and vegetation that has grown there. Human-made soils reflect human influence on their formation, mainly in urban environments, which often results in the presence of small amounts of manufactured materials, such as brick fragments, paint flecks, plastics or fly ash. Soil components and resultant characteristics are diverse, and this potential diversity and variation has enabled forensic soil examiners to distinguish soils that otherwise may appear similar to the untrained eye (e.g., Murray and Tedrow, 1992; Pye, 2007; Ruffell and McKinley, 2008; Ritz et al., 2008; Murray, 2011; Fitzpatrick, 2013; Dawson and Mayes, 2014; Donnelly et al., 2021). Traditional soil science is a different discipline from forensic soil science, the latter requiring professional knowledge of the discipline of soil science, as well as knowledge of the legal aspects. These include adherence to legal protocols, an understanding of crime scene protocols, evidential requirements of forensic practitioners, chain of custody, and the nature of legal constraints, including effective communication in court. It is critical to establish the most appropriate methods to use, both for examination, analysis and for the evaluation of any resultant data and how to communicate those findings in a court of law (Dawson et al., 2021). Soil and related materials can be used for intelligence work such as assisting police in search operations with soil recovered from a spade, for example (Aitkenhead et al., 2014; Harrison et al., 2016). In addition, comparison of trace evidence analysis between soil found adhering to a questioned item such as a suspect's shoe or vehicle with soil from a crime scene and alternative locations, enables evaluation of the likelihood that the questioned soil originated from the crime scene or alternatively, another proposed location (Dawson and Morgan, 2015).

The history of forensic soil science

Forensic soil science has only recently (since the 1990s) been accepted in courts of law. However, the principles have been used since Roman times where hooves of enemies' horses were examined to ascertain from where they had most likely traveled. The first published case of a forensic soil comparison was with sand characteristics which helped police solve a crime that took place on a Prussian railroad in April 1856. A barrel containing silver coins had been emptied and refilled with sand during transit and Prof. Christian Gottfried Ehrenberg sampled soil from all the railway stations along the line, using a light microscope. He examined features of the soil particles (color and shape) and compared the soil substituted in the barrel to the sand sampled at the rail stations, narrowing it down to the one from which the sand originated (Science and Art, 1856). Sir Arthur Conan Doyle published several stories involving his fictional character, Sherlock Holmes, where forensic soil comparisons were carried out as part of criminal investigations. Holmes's assistant Dr John Watson described him as being able to "tell at a glance different soil from each other. After walks, has shown me splashed upon his trousers, and told me by their color and consistence in what part of London he had received them." In the early 1900s George Popp, a forensic scientist in Frankfurt, successfully examined soil, minerals, and dust from items of clothing to help solve two criminal cases (Murray, 2011). In 1893, the Australian scientist Hans Gross suggested that "perhaps dirt on someone's shoes could tell you more about where a person had last been than toilsome inquiries". Soil information was starting to be used by police in the United States, United Kingdom, Russia, and Australia between the 1900s and the 1990s. However, soil analyzes had become very specialized and expensive for use in most forensic laboratories and forensic agencies worldwide. As a result, soil forensic evidence was often missed or ignored, often buried within other trace evidence. Soil science techniques were generally not deployed on complex forensic cases until the 2000s. At that time, it was mainly mineralogy and palynology that was used, often by individuals within university departments. The recent surge in research around the world into the mineralogy, geochemistry and biology of forensically important soil materials has helped bring forensic soil science to the forefront (Dawson and Hillier, 2010; Donnelly et al., 2021). Forensic soil science is now being used to deliver powerful forensic evidence with significant benefits to criminal investigations in many countries across the world (Di Maggio et al., 2017).

Theory of soil transfer

The transfer of trace evidence is governed by the Locard Exchange Principle, which states that "when two surfaces come into physical contact there is a mutual exchange of trace evidence between them" (Locard, 1930). The exchange can take the form of soil from a location transferring to the shoes of a person who walked through that area. These types of transfers are referred to as primary transfers (e.g., evidence is transferred from the soil surface to the shoe and later recovered from the shoe, such as in the tread of the sole). After the point of primary transfer, any subsequent movements of that soil material such as from the shoe to the footwell mat of a vehicle are referred to as secondary transfers. These secondary transfers of soil materials can be significant in evaluating the nature and source(s) of contact. Soils can provide information linking (or excluding) persons to or from crime scenes, control sites, or alibi sites. Higher order transfers such as tertiary transfers of soil can also occur, such as from a scene to footwear to a carpet surface and to another person walking and encountering that area. Although it is useful to be aware of such high-level transfers, they can present interpretative problems because the ultimate source of trace evidence may be difficult to identify (Murray, 2011). Most cases involve primary or secondary associations between questioned items such as footwear, vehicles, tools such as spades, and clothing to identify locations of interest. Soil trace evidence can link an object or person to the scene of a crime, as well as rule out an individual suspect or to support a proposed alibi.

Soil characteristics

Soil materials can potentially provide powerful 'contact trace' evidence that assists in criminal investigations. They can be distinctive, have a strong likelihood of transfer and persistence (especially when wet and when they contain some clay and organic matter), can be nearly invisible and be relatively easily collected and characterized. There are thousands of different soil types, with a vast range and complexity that enables forensic soil examiners to distinguish between individual soil samples submitted for examination and characterization. These characteristics vary horizontally across a landscape and vertically with depth down a soil, which can be useful for comparison at a burial site. Human created features within soils (artifacts such as paint and plastics) can make soils even more distinctive. Soil also usually has a strong capacity to persist, particularly the fine sized fractions (clay and silt) and the organic matter in soils. When the soils are wet, they transfer and persist more easily than when dry. The presence of small amounts of fine soil material is often not visible to the naked eye, contrasting with other more colorful trace materials such as blood and paint.

Soil sampling at a crime scene

The relevance of soil evidence should be accurately documented and collection and preservation of any soils and related materials must be maintained rigorously to retain the integrity of the soil evidence as part of the chain of custody (Ruffell and McKinley,

2008). The location and number of reference samples to collect from individual crime scenes or alibi sites will depend on several factors—including activity, variability, soil type, weather conditions, vegetation cover, contact points such as footwear marks, tyre treads, all of which will affect the depth of sampling, number and size of samples to be collected and type of tool/container used (see Fig. 1 and Pirrie et al., 2021a, 2021b). If the scene involves a burial site, samples will need to be collected at any potential contact points with tools such as spades, and from every soil horizon, at the base of the burial environment and from the surface layer where contact with footwear may have occurred.

Soil sampling schemes can be divided into ‘targeted sampling’ of localized areas where distinguishing features are noted in the soil (e.g., tyre marks) or on some other surface (e.g., a footprint on the floor) or ‘random sampling’ in cases where there is an absence of obvious features at or around a location of interest (i.e., a systematic sampling of the location to obtain an unbiased sample). Clean sampling tools should always be used (i.e., an alcohol wiped trowel). Artist’s palette knives are useful for sampling very thin layers of mud or surface contact soil (Fig. 2). It is recommended that samples are stored carefully for transport in ‘rigid

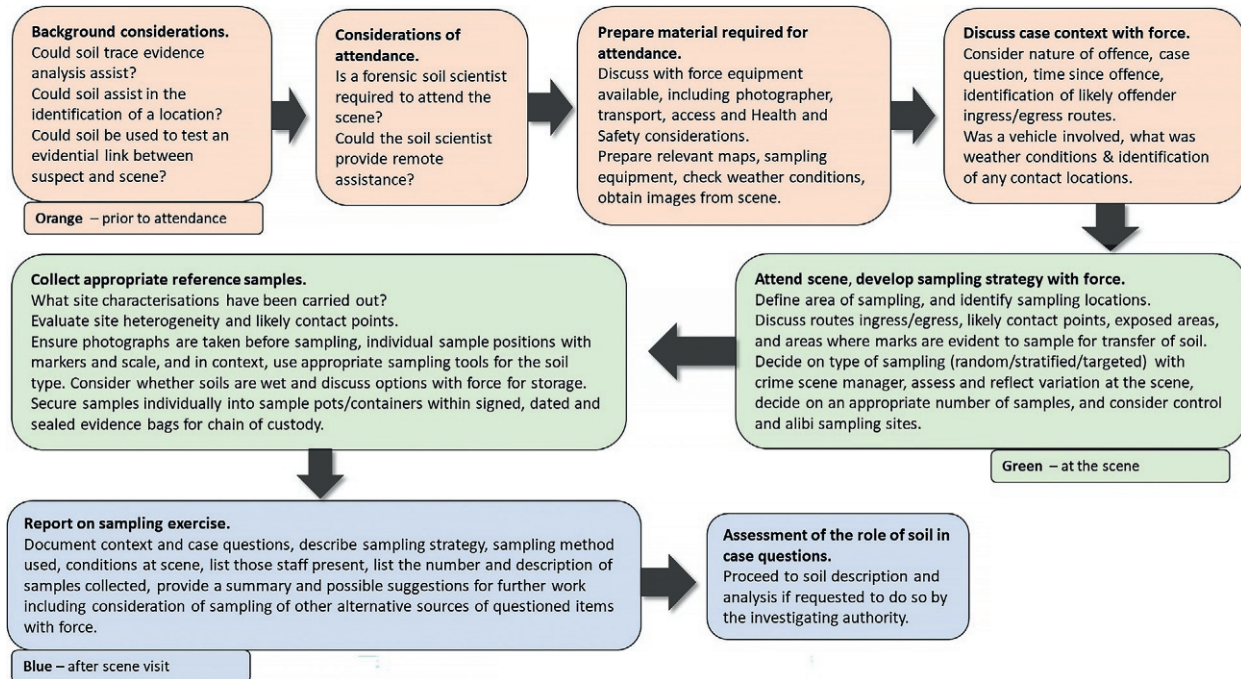

Fig. 1 Proposed considerations for soil sampling at a crime scene. Also see material in Pirrie D, Ruffell A, Dawson LA and McKinley J (2021) Crime scenes: Geoforensic assessment sampling and examination. In: Donnelly L, Pirrie D, Harrison M, Ruffell A and Dawson L (eds.), *A Guide to Forensic Geology*. Geological Society: London.

Fig. 2 Example of the method of collection of a surface soil sample at a crime scene. Lorna Dawson.

plastic containers' rather than loose within bags to help retain the soil structure to allow sub sampling of individual layers in soil stratigraphy if appropriate. Although not always practical, if the soil is in a moist condition, the sample should ideally be air dried before packing. If biological material such as plant leaves are within the soil sample, it should be packaged using clean cardboard box or paper bags and stored at $\sim 4^{\circ}\text{C}$ to prevent deterioration.

Soils can be collected by scene of crime officers at crime scenes, by forensic examiners when examining items of physical evidence (such as a questioned item of footwear) for other evidence such as blood or fibers, or by the forensic soil scientist. (See Fig. 5; Pirrie et al., 2021a).

Soil examination and methods of analysis

In the soil science laboratory, a magnifier lens and binocular light microscopes are usually the first piece of equipment to be used (after viewing the samples with the naked eye) (Fig. 3). Soil materials are first described using conventional soil pedological features (i.e., soil color, texture, structure). Soils can then be characterized using a range of analytical methods. Stones and vegetation fragments are removed with sterile tweezers and can be described separately if required. It is important that individual soil traces with similar color and texture are recovered separately to provide the most appropriate comparison with single source reference samples from any site of interest (Fig. 4).

Fig. 3 Examination of an item of footwear for subsequent analysis. Lorna Dawson.

Fig. 4 Sampling and recovery of soil and vegetation from an item of footwear for subsequent analysis. Lorna Dawson.

To characterize the inorganic fraction quantitatively, methods such as X-ray diffraction (XRD) (for the mineral profile) or inductively coupled plasma (ICP) (for the elemental profile) can be used, while chromatographic methods such as gas chromatography (GC) can be used for the organic fraction profile (Dawson and Hillier, 2010; Dawson, 2017). Where only a trace amount of sample is available, Fourier Transform Infrared Spectroscopy (FTIR), Raman spectroscopy, Scanning Electron Microscopy (SEM), Energy Dispersive X-ray Spectroscopic Analysis (EDXA) can be used. The method adopted depends on many factors, including the size and condition of the questioned samples, equipment available and the characteristics of local soils (Fig. 5). If possible, the methods chosen first should be non-destructive, followed by quantitative methods where within sample variation can be characterized and compared with related quantitative databases. The use of Standard Operating Procedures (SOPs) is recommended (e.g., Testoni et al., 2019) as are standardization and accreditation of methods where possible.

Methods for characterizing soils for a forensic comparison, broadly involves subdividing methods into four stages, each comprising several steps and involving a combination of techniques (e.g., various descriptive or morphological and analytical methods). Consequently, soil characterization requires a multidisciplinary approach, which combines descriptive and analytical methods together with information on spatial context such as that in the maps of geographical information systems (GIS). The progression of a soil examination through each of the stages (Fig. 5) will depend on several factors such as the amount of sample available, the environment and land cover at the scene, results from the initial stages of examination and the digital information available. Several forensic practitioners have suggested a similar sequence or succession approach of sediment or soil analysis for exclusionary or comparative forensic investigations. Recently a guide was published by the European Network of Forensic Science Institutes (ENFSI APTST, 2019), and a book was published by the Geological Society of London through the International Union of Geological Sciences, Initiative on Forensic Geology (IUGS, IFG) group, outlining guidelines to options for search and evidence collection, analysis, and reporting (Donnelly et al., 2021). However, there is no one single authoritative scene of crime manual or laboratory methods manual for soils; the justice system of the country in which the work is being carried out will dictate many of the most appropriate methods and approaches adopted. The approach and method of each forensic situation should be taken on its own merits (such as size and condition of questioned sample, type of soil, degree of mixing, etc.) and the approach chosen according to existing conditions. However, any approaches adopted must involve standard approaches for the recording, describing, and chain of custody of case materials.

Forensic soil comparisons of a questioned soil sample from an unknown origin with one or more soil samples of a known origin (such as a crime scene or alibi location) are preferably based on several properties. This enables the expert to evaluate the significance of observed similarities and differences, and to arrive at a conclusion regarding a possible association (See Fig. 2; Pirrie et al., 2021a, 2021b). Soil can be used to indicate or compare provenance, and therefore be used as 'intelligence' to narrow areas of search during an investigation and subsequently for trace evidence comparison if required by the investigating authority. Evaluative comparison of soil on one article of evidence compared to soil on another, or compared to a known location, can and has been used as evidence in many courts of law (e.g., Dawson and Hillier, 2010; Dawson and Mayes, 2014). Forensic evidence is often available only as very small amounts of soil material and will therefore often limit the evidential strength of such comparisons.

Most forensic cases involving soil materials are usually complex and the challenges of associating relevant information from one source with another often requires the application of sophisticated field and laboratory methods and soil science discipline-based knowledge. The methods used for comparing soil samples must be practical, inexpensive, accurate, and applicable to both small and large samples.

Soil evidence

The aim of forensic soil analysis is to test for a potential association (link) between a soil sample taken from a questioned item (e.g., shoes, clothing, tools, or vehicle) with a specific location such as a crime scene. Methods of sample collection and analyzes chosen must be able to discriminate between soil samples from separate locations. All sampling methods, sample storage security, soil characterization, analytical methods, and data handling must be subject to rigorous procedures. They should be transparent and have a secure chain of custody, so that they can be discoverable and able to be questioned if presented in court (Ruffell et al., 2021). The forensic investigation of soil usually involves site investigation and characterization; soil sampling to represent the crime scene and additional potential contact source locations; soil collection and recovery of soil from one or more questioned items; soil characterization, evaluation, and comparison, and reporting and communicating the results found, often to a court.

Soil databases

Mapping of the surface and subsurface of both natural and human-made soils provides crucial information in relation to geographical location, function, land use, and management. In many countries in the world, soil data have been encoded into computer-compatible form. In Scotland the SE web is a free source of soil data (Home | Scotland's environment web) and for the UK the UK Soil Observatory is available (UK Soil Observatory). Each nation has their own maps and digital data, with varying extent and resolution. One of the main concerns with the use of national soil databases for criminal investigations is that they were usually created for agricultural or environmental reasons, and are therefore often lacking in surface soil characteristics and the characteristics mapped (e.g., soil carbon, pH, texture) are often not those used in forensic soil science. For that reason, many forensic soil scientists

Fig. 5 A proposed sequence for soil examination, analysis, comparison, and evaluation to assist with Criminal Justice Investigations. Also see ENFSI APTST (2019) *Best Practice Manual for the Forensic Comparison of Soil Traces*. Best Practice Manual for the Forensic Comparison of Soil Traces (enfsi.eu); Donnelly LJ, Pirrie D, Harrison, Ruffell A, Dawson LA (eds.) (2021) *A Guide to Forensic Geology*. Geological Society: London, Special Publication.

have created their own databases containing representative samples across rural, urban, and peri-urban areas, including surface samples, with the methods that they most commonly adopt for forensic case work.

Soil classification

Soil classification provides a structured conceptual framework for describing and understanding soil properties and soil formation, and helps to organize soil knowledge, often through national soil survey. The two most widely used international soil classification systems are the World Reference Base (WRB) for Soil Resources (IUSS Working Group WRB, 2015) and Soil Taxonomy (Soil Survey Staff, 2014). The WRB is an international system for soil classification and developed under the direction of the Food and Agriculture Organization of the United Nations (FAO). However, many countries also have their own national classifications. Soil maps show the spatial distribution of soils across the land and were originally produced by field surveyors who walked over the landscape, looking at the soils and other features such as vegetation and topography, drawing boundaries between the different soil types. Mapping methods have evolved over time, and now techniques such as aerial photography and satellite-based global positioning systems (GPS) are used and are linked with analytical databases. Soil maps are produced at a range of scales from those covering large areas (countries and regions; 1:100000 or smaller scale) to detailed areas such as farms or parklands (1:10000 or larger scale). Each soil has its own characteristics which can be described by the soil scientist (e.g., morphology, mineralogy, and organic matter composition). These classifications allow us to narrow down areas in search operations, such as through the comparison of analytical attributes of a questioned soil with the attributes of samples held within the spatially referenced databases.

Human-made soils

Human-made soils are those that contain buried objects, or artifacts, derived from human habitation and management of urban environments. These can be particularly important in forensic case work because many crimes are committed in urban and peri-urban areas. Other terms used in soil classification systems include 'human-altered' and 'human-transported' soils (HAHT) in Soil Taxonomy, 'Technosols' (WRB), while Soil Taxonomy and the Soil Classification for England and Wales includes a 'man-made' soil category. The soil survey for Scotland does not provide for human-made soils in its taxonomic system. The Anthroisol soil group relates to the effects of long-term cultivation on soil formation, whereas the Technosol soil group is characterized by the presence of materials, which have been manufactured or relocated by humans, therefore, Technosols would more obviously represent most urban soils. Technosols are also present in non-urban environments. Anthropogenic soils are characterized by strong spatial heterogeneity, as a result of the many different potential inputs of manufactured materials (e.g., brick fragments, fecal material, fly ash, plant debris, compost, plastics, or toxic wastes) and mixing of the original (natural) soil material (e.g., gardens, parks, or cemeteries) with introduced materials such as compost and sand and can be particularly discriminating in forensic investigations (Dawson et al., 2019). Soils from mines or quarries are another class of anthropogenic soils, which are strongly influenced but are not necessarily found in or near cities. Anthropogenic soils are diverse, heterogeneous, and complex, which enables forensic soil examiners to distinguish between soils, which may otherwise appear similar. They can also often reflect a history of multiple influences, which has been very useful in understanding and characterizing soil differences in soil forensic comparisons.

Chain-of-custody

Of paramount importance in both soil collection or sampling and soil characterization or evaluation is continuity of evidence or chain-of-custody, which must be maintained and always documented throughout an entire soil forensic investigation. Preservation of soil material must be maintained to retain the integrity of the soil materials. Consequently, secure sealing of dry soil samples in sample bags or bottles with tamper-indicating serrated evidence tape and sample storage is vital. Secure sample storage and rigorous procedures ensure that information about each sample is unambiguously retrievable and can be presented in court with certainty (Fitzpatrick and Donnelly, 2021).

Initial description and characterization of samples

Initial screening (i.e., morphological comparison examination, qualitative color comparisons) of whole soil samples is to provide a visual comparison of samples (i.e., hand-held samples or specimens, soil profiles, and samples or specimens under a stereo-binocular light microscope) (ENFSI APTST, 2019). To do this, the soil must first be described systematically and characterized using standard soil morphological descriptors and tests such as color, consistency, structure, texture, segregations or coarse fragments (charcoal, ironstone, or carbonates), and abundance of roots or pores; to deduce whether a soil sample can potentially be used as evidence. These soil morphological descriptions follow strict conventions whereby a standard array of data is described in

a sequence, and each term is defined according to both International, (e.g., USDA Field book) and National standard systems for describing and sampling soils.

Soil inorganic analysis

Characterization of the soil inorganic fraction is usually carried out following sample selection and size fractionation through a standardized mesh-sized sieve (usually 1 or 2 mm). In addition, other selected methods, such as X-Ray Diffraction (XRD), Diffuse Reflectance Infrared Fourier Transform (DRIFT) or ICP and XRD are often used for the identification, characterization, and quantitative analyzes of minerals in soil (if enough sample is recovered). The advantage of XRD methods in forensic soil science is based on the unique character of the diffraction patterns of crystalline and even poorly crystalline soil minerals that they provide. Elements and their oxides, polymorphic forms (e.g., anatase and rutile polymorphic forms of TiO_2 , titanium dioxide) and mixed crystals can be distinguished by this semi-destructive examination. Part of the comparison involves identification of as many of the crystalline components by reference to a database of XRD data or to a local collection of standard reference diffraction patterns, coupled with expert interpretation. The XRD patterns can be compared for different soil samples to delineate how closely the samples relate to each other. Infrared (IR) spectroscopy is nondestructive and can be rapidly applied with the mid-infrared part of the electromagnetic spectrum, which is sensitive to organic materials, clay minerals, and quartz because of the absorption of infrared light at the vibrational frequencies of molecular functional groups constituting these materials (Dawson and Hillier, 2010) although they are not quantitative. Magnetic susceptibility methods, which have become a powerful tool to detect magnetic materials in soils (e.g., maghemite, magnetite) that are present at amounts below the detection limits of both XRD and IR, can also be applied (Murray, 2011).

Soil organic characterization

Characterization and the quantification of the organic fraction in soil samples can be carried out using several approaches. The quantification of soil wax markers, although destructive, can be carried out on samples <45 mg in size, and enables the analysis of individual aggregates or peds, which allows a better comparison between traces of soil. The *n*-alkanes and alcohols in soil reflects both current and past land use at a particular site. These, in general, provide information at a more local scale than inorganic methods on petroleum hydrocarbons and fecal material within soil samples (Dawson, 2017; McCulloch et al., 2018).

The soil pollen profile can also be used to characterize the organic component of soils, but it requires transparency of associated databases of pollen profiles to enable any evaluation to be carried out (Ezegbogu, 2021; Uitdehaag, 2021) which is not always available in all countries. In addition, more contemporary approaches such as Raman spectroscopy, stable isotope analysis and DNA metabarcoding are being developed. But there are major challenges with these methods that include a lack of optimization to forensic expectations and lack of robust data interpretation (Ezegbogu, 2021). Several research papers have been reported to show that the DNA profile of a soil bacterial community could be obtained from samples of soil recovered from potential crime scenes (e.g., shoes or clothing), and could be compared with profiles that are representative of the site of collection. There are issues, however, with DNA extraction for the comparison of soil type, and the very small scales of temporal and spatial variation (Demaneche et al., 2017). At present, the analytical procedures are not sufficiently robust for results to be acceptable in courts of law.

Soil particle characterization

In many forensic investigations of soil, the amount of soil available for analyzes may be extremely small (e.g., thin coatings or single particles weighing around 0.5–5 mg). The use of petrography is a major and precise method of studying and screening soils for discrimination in forensic science and is used in several countries across the world. Around 50 common minerals can be observed by the naked eye. A hand lens or low power stereo-binocular microscope enables the forensic soil scientist to detect the mineral properties better (particle shape and surface texture) and provide more accurate mineral identification. The petrographic microscope is also used for characterizing microfossils such as pollen grains, grass spores, opal phytoliths and diatoms. However, these detailed identifications may represent only a small part of the source sample and require specialized training, are subjective, and will be unlikely be part of national forensic laboratories.

Evaluation of soil information

Landform and soil mapping can be used by forensic soil scientists to integrate and extrapolate soil information from one scale to the next to create a coherent model of soil information from microscopic observations to the landscape scale (e.g., using soil, geological maps, terrain analysis, remote sensing, and geophysics). This combined information is used for geographic sourcing to identify the origin of a sample by placing constraints on the environment from which the sample originated.

There are many ways to evaluate soil evidence as to its evidential strength, and each country has its own approach, ranging from simple 'cannot be excluded as sharing a common origin' to Bayesian likelihood ratio determinations (ENFSI APTST, 2019). The types of methods applied and types of soil, along with available relevant validated databases, and the type of legal system will influence the system adopted (Dawson et al., 2021).

Communication

Investigators are often trying to establish if there are linkages or associations between victims, suspects, crime scenes, and individual items, which is the case with any form of physical evidence. Raymond Murray's book 'Evidence from the Earth' provides many high-profile case examples in which earth materials and related methods have contributed significantly to solving cases from around the world. Soil evidence has already proven useful in helping to solve criminal, civil, and environmental cases. Innovative ideas, methods, or applications of field and laboratory approaches in soil science have been critical in developing coherent, predictive results and the building of soil models from microscopic to landscape scales, to solve difficult soil-based investigations at a range of scales, often involving complex issues. In particular, in countries where the legal systems involve juries as the triers of fact (e.g., the United Kingdom, Australia, the United States of America), the expert witness should be able to explain their findings in an easily understood manner so that any jury member can understand what the evidence can tell us, and of equal importance, what the evidence is not able to tell us (Dawson et al., 2021; Dawson and Gunnicliffe, 2017). Soil is a complex entity, but the duty of the expert witness (including that of the forensic soil scientist) is to the court and along with that duty is the need to deliver the results and opinion in a clear and straightforward way so that it is understood.

Concluding remarks

Forensic soil science is the application of soil science within the context of the law. It is currently used in many countries, including the United Kingdom, Australia, the Netherlands, Germany, Spain, Italy, the United States of America, and Russia, and is developing rapidly across other regions of the world. Soil materials can be used in forensic investigations to evaluate potential associations to support law enforcement agencies in investigations of criminal, environmental, wildlife and serious and organized crime. Soil recovered from a questioned item with an unknown history can be compared with known locations such as a crime scene. Forensic soil science is used to assist in search operations where soil can help to narrow down areas on which to focus the ground search activities (provenancing). It can also be used for trace evidence comparison, where a questioned soil recovered from an item such as a vehicle, footwear or clothing can be compared with known samples such as from a crime scene. Soil forensic investigation involves the collection of soil samples from a crime scene location and the recovery of soil from questioned items, followed by a process of soil description, soil characterization and comparative analyzes. Soil samples used in forensic case work require careful collection, consistent with standard forensic best practice, followed by analysis and interpretation by a suitably qualified and experienced forensic soil scientist. Soil characterization should involve a staged strategic approach, which normally involves visual examination of the soil's physical characteristics, (i.e., color, texture and morphology), followed by chemical, physical and/or biological analysis, using the most appropriate technique for the soil type and soil conditions under consideration. Individual components within the soil can be identified and compared, such as leaf fragments, hydrocarbons, fecal substrates, minerals, pollen grains or recovered artifacts. Integration and extrapolation of the soil information can be scaled up to create a model of soil information, which often involves soil and land cover maps and geographical information systems (GIS). Progression of a soil forensic examination through each of the stages depends on the amount of sample available, the conditions of the sample, the case question, and the outcome of the initial stages of the examination. Established concepts, standardized approaches and professionalism have been developed in soil science and should be carefully applied regarding the legal context to allow the appropriate and safe application of soil science within the criminal justice systems worldwide.

Abstract

The chapter first analyses what is meant by the term soil governance and what the particular challenges are. It addresses the national and regional levels of soil governance, together with an explanation of the existing regulatory structure at the international level. As sustainable management of soils is inextricably linked to and carried out based on the conditions specific to a location, national regulation is most essential. To provide more specific insights, this chapter also explores – in an excursus – soil governance in Germany and an assessment of the tools and sources of information, including databases. The interlinkage of international trade law and sustainable soil management is also explained.

Key points

- Overview of soil governance at national, regional and international level
- Challenges of soil governance
- Insights to the regulatory concept in Germany
- Importance of effective administrative arrangements
- Cultural and ethical perceptions on soils
- Methodological considerations

Introduction

The perception of soils has changed significantly over the last 10 years. Previously, soils were often regarded as the poor, in the sense of being neglected, cousin of water, air and biodiversity (Ginzky, 2020). Soils were seen as ‘dirt’; the many social and ecological functions they provided were taken for granted and therefore, in a way, ‘overlooked and not valued.’

Even worse from a conservation perspective, soil was often only perceived as land, which could be possessed and owned by private persons or institutions, or by municipal or state entities. These owners and or users were often regarded as having an exclusive and unlimited right to use and exploit the land and the soil beneath it (Ruppel and Ginzky, 2021; Ginzky et al., 2019). Thus, a responsibility of the land owner or user to maintain the soil quality was not assumed.

There were several processes which led to a new perception of soils. The food crisis at the beginning of this century, and all its consequences, triggered this new development as it became clear that fertile soils are a precondition for food security (Ginzky, 2020). States and private investors also started to try to secure access to land in other countries for future needs, referred to as ‘and grabbing,’ thereby often jeopardizing the interests and necessities of the local communities (Windfuhr, 2016; Tamasang, 2022). Moreover, scientific evidence has shown that fertile soils are the second largest biological carbon sink on the planet; thus, they are indispensable to climate mitigation and adaptation processes (IPCC, 2018, 2020). In this context it also became clear that fertile soils are needed for the production of plants for renewable energy and potentially for the uptake and sequestration of already emitted greenhouse gases (IPCC, 2018). In addition, with regard to the dramatic biodiversity crisis faced globally, studies have emphasized that soils host an almost infinite amount of biodiversity (IPBES, 2018). Given all of these factors, an overwhelming consensus developed that the ongoing land and soil degradation needs to be stopped and that the maintenance and enhancement of soils are a precondition to fighting these various crises and implementing truly sustainable development.

Starting around 2010, several scientific and or political fora started to discuss and promote the topic of soils and their social and ecological services. One important move was the Berlin Call for Action of 2011. Several relevant international bodies and entities assembled in Berlin, such as the United Nations Convention to Combat Desertification (UNCCD), the Food and Agriculture Organisation (FAO) and others, and concluded with a call for more soil awareness, joint efforts to develop a better scientific understanding on soils primarily through the selection of data and for more soil governance.¹ In the same year, the UNCCD took up the issue, working on the concept of a “Zero land degradation world” (Lal et al., 2012; Hannam, 2022). In 2012, world leaders at the Rio + 20 Conference jointly recognized the “economic and social significance of good land management” and stressed that “desertification, land degradation and drought are challenges of global dimension” as well as “the need for urgent action” (United Nations, 2012). September 2015 was then another milestone. The UN General Assembly in New York adopted the 2030 Sustainability Agenda (United Nations, 2015) with the 17 Sustainable Development Goals (SDGs), including 169 targets. In target 15.3 the world leaders agreed to strive to achieve a “land degradation neutral world” by 2030. The UNCCD subsequently established itself as the international lead organization for the implementation of this objective at its Conference of the Parties at the end of 2015 (Boer et al., 2016).

The importance of ‘dealing well with soils’ was furthermore promoted and brought to the fore by a sequence of so-called “Global Soil Weeks” – large workshops with international attendance that took place annually in Berlin and Nairobi between 2012 and 2019.² In addition, several reports by the Intergovernmental Panel on Climate Change (IPCC) and the Intergovernmental Science-Policy Panel on Biodiversity and Ecosystem Services (IPBES), in particular after 2018, underlined the interface between sustainable soil management, and both climate mitigation and adaptation as well as the biodiversity crisis (IPCC, 2018 and IPBES, 2018).

Awareness is a good thing. Nevertheless, sustainable soil management requires considerable knowledge, political will and good governance. As pioneers on the topic of soil governance, Ben Boer and Ian Hannam have to be mentioned. In the early years of this century, they dedicated a great deal of work to analyzing soil law at the international as well as the national level (inter alia Boer and Hannam, 2003 and Hannam and Boer, 2002). The *International Yearbook of Soil Law and Policy* has now published five volumes, each more than 400 pages, and SoILEX, a database of existing legal instruments on soil protection throughout the world provided by the FAO, are important mechanisms to promote discussion as to appropriate regulatory instruments and concepts, and to create a platform for exchange and debate.

This chapter is about soil governance. The intention is to provide an instructive overview on its most important aspects, primarily for non-lawyers. The chapter includes what is meant by the term soil governance and the particular challenges, the existing regulatory structure at the international level, followed by that at the national and regional levels, in an excursus, soil governance in Germany, the interlinkage of international trade law and sustainable soil management, and finally some concluding remarks on the interface of soil governance and transformative processes towards sustainability and climate neutrality.

²<https://globalsoilweek.org/>.

The background of soil governance

Before discussing regulation in itself, it is important to understand first what 'soil governance' means. Second, it is important to emphasize the potential value of soil for society. In this context, the social and ecological services that soils provide must be highlighted. Third, the particularities which render soil governance challenging should be mentioned. Finally, the potential drivers and soil threats need to be explained.

Definition of soil governance

Governance is a term which needs clarification. The FAO defines soil governance as follows: "Soil governance concerns policies and strategies and the processes of decision-making by nation states and local governments on how the soil is utilized."³ In this chapter soil governance is taken to include legal provisions, and organizational and institutional arrangements that are intended to regulate the use of soils. A full picture of soil governance would also need to entail the financial resources of relevant entities, the interplay between various actors, such as policy makers, scientific institutions and civil society, as well as cultural and religious conventions and perceptions. Soil governance can be found at all levels, municipal as well as national, regional (transboundary) (for example, the European Union and the Alpine region) and at international level.

Value of soils for society

Until recently, soils have not been adequately valued. This undervaluing of soils has been the dominant perception for a long time. There are several reasons. Soils have been primarily perceived as the dirt under our shoes. Others may have seen soils as a given and therefore 'eternal' or 'inexhaustible.' Others may have taken the view that nature is there to serve the purposes of human beings.

A more realistic view tells us that soils are indispensable for the future of human beings, which will only be possible through sustainable development as they provide the following services (Ginzky, 2020):

- Basis for food production and production of plants for renewable energy
- Carbon sequestration, therefore important to climate change mitigation
- Biodiversity host
- Vital role in world's biological cycle by inter alia storing nutrients and filtering groundwater from hazardous substances
- Climate adaptation, particularly in urban areas
- Water storage in case of draught and extreme rainfall
- Basis for nature and recreational areas for human beings
- Cultural and biological archive

Without fertile or healthy soils, inter alia, food security, climate mitigation and adaptation as well as maintenance of biodiversity could hardly be achieved. Inadequate sustainable soil management may thus lead to poverty, migration within or beyond national boundaries and even political or military conflicts about natural resources or due to societal instabilities (Ginzky, 2020).

Furthermore, and it is not to be underestimated, soils as part of nature are culturally rich and historically significant. Culture relates to the traditions, emotions, societal behaviors and even art influenced by, deeply ingrained and tied to soils. They also serve as an archive of human history, containing biological remnants from past (mis)uses and societies. Loss of soil could then also mean a loss of culture and or history (Heuser, 2017).

Soils are generally immobile and local, however, erosion by wind or water may move them to another location. Despite being generally immobile, soils provide the above mentioned social and ecological services which may have a direct or indirect transboundary effect. Hence, the potential negative consequence of soil degradation, such as food insecurity, political conflicts, climate change, are in essence transboundary (Flasbarth, 2016).

Global status of land and soil degradation

Looking at the current state of soils worldwide, figures of the steady or even accelerating rate of land degradation are alarming. About one third of the world's soils are already affected (Ginzky, 2016). An area the size of Italy has been and will be, without intervention, continuously degraded each year (Linz and Lobos, 2016).

Challenges of soil governance

Soil governance faces particular challenges. First, most human activities affect soils, such as agriculture, residential development (urban or rural), transport and manufacturing. (Ginzky (2016), p. 3).⁴ Almost any use of soil will cause degradation to some extent.

³<https://www.fao.org/global-soil-partnership/areas-of-work/soil-governance/en/>.

⁴One exemption is if people act in aquatic settings. For example, fishing or shipping do not necessarily have a direct effect on soils.

Soil governance is therefore a cross-cutting issue as most human activities need to be considered with regard to sustainable soil management.

A second aspect which poses specific challenges to soil governance is that soils are mostly owned by individual persons, private companies, local communities or state entities. For a long time, the overall perception has been that the plot of land which entails the soil belongs to the owner, who has an exclusive and somewhat untouchable right to exploit this 'resource.'

As a third challenge, insecure tenure rights are an additional challenge in many regions of the world (Ginzky and Ruppel, 2021; Munyuki-Hungwe, 2020). Insecure tenure may cause many hindrances to sustainable soil management as user rights, responsibilities and accountability remain unclear (Windfuhr, 2016).

Fourth, one must not forget that soil as a resource is often of high economic value as it can be exploited in many respects, such as, inter alia, for building houses, infrastructure or industrial facilities, growing food (or nowadays also fuel crops) or for grazing as well as receiving carbon credits for carbon uptake (Bodde et al., 2020). It immediately becomes clear that governance for sustainable soil management may conflict with the economic interests of individual users or owners of soils as they do not want to see their individual exploitation rights limited or restricted.

And last but not least, a more scientific issue: There are many different types of soil which differ significantly with regard to their components, structure and other aspects. Thus, each soil type carries its own characteristics, specific resilience and vulnerabilities with regard to different uses. These different natural realities need to be considered when drafting soil governance instruments as 'one-size-fits-all' is neither appropriate nor effective.

Soil threats and drivers

Most human activities have effects on soils. There are, however, a few main factors that control the degradation of soils. First, unsustainable agricultural and forestry practices are a major factor in most parts of the world. These unsustainable practices could have completely different motives or reasons: lack of knowledge regarding extent or severity of impacts or consequences, necessity due to poverty, inadequate technology as well as economic benefit or greed.

Second, urbanization typically causes negative effects on soils, posing threats such as sealing (i.e. paving over healthy soils with concrete foundations) and contamination. The same applies to land taken for infrastructure, such as streets or railways, and industrial uses. Mining may also provoke degrading processes on soils. Finally, effects from climate change or the biodiversity crisis, such as unpredictable seasonal weather, extreme weather events or new pests, could have detrimental effects on soils (Ginzky, 2020). Furthermore, poverty and hunger on the one hand and weak governance on the other could be drivers of soil degradation (Orubebe, 2020; Ruppel and Ginzky, 2021).

Different threats to soil arising from these various uses may be identified. The ability to categorize the different risks posed to soils may help to focus the debate better on potentially effective regulatory concepts and instruments. The EU Thematic Strategy for Soils of 2006 differentiated eight types of soil threats, including: soil erosion, decline in organic matter, local and diffuse contamination, sealing, compaction, and decline in biodiversity, salinization, floods and landslides.⁵ Water scarcity or drought, eutrophication as well as changing biodiversity were not included in that policy document, but they should be seen as additional soil threats needing to be dealt with through soil governance.

Summary

Soil governance is a complex task for several reasons: it is cross-cutting, it has been undervalued, it may potentially conflict with economic interests, it must cover diverse types of soils, etc. At the same time, soils provide numerous social and ecological services which are of great value for society. Soils are indispensable, and this renders soil governance a major challenge.

There is no blue print which fits all states. The challenges faced by each state with regard to their different main soil threats and drivers, as well as their necessities and priorities should be the starting point for their individual sustainable soil governance processes. Thus, these aspects are also decisive to determine which specific actions are appropriate and needed for the national contexts.

Soil governance at the international level

International environmental law is very different from national law as there is no single legislator, but states who decide on the topics, the level and the structures of international cooperation. Thus, international environmental law is mainly entailed in international treaties, such as the United Nations Framework Convention on Climate Change (UNFCCC).⁶ Provisions in international treaties are only obligatory for states that have signed and ratified the respective treaties. For citizens and legal entities, provisions of international treaties only become mandatory after they have been transposed into national legislation (Bodde et al., 2020).

⁵EU Commission (2012).

⁶The Text of the UNFCCC may be found at: www.unfccc.int

The preparation and negotiation of international treaties is very time- and resource-consuming as all states follow their own political priorities in these discussions. All states must accept the various provisions in such treaties, therefore, compromises have to be negotiated and reached to gain consensus.

Most international environmental treaties have established their own organizational entities: *inter alia*, a Conference of the Parties, which meets annually or biannually and is normally the political body of the treaty regime; a Secretariat, which is in charge of facilitating the negotiations amongst the State Parties and for the Convention's continuous management; and a scientific advisory body (Bodle et al., 2020).

In addition to treaty provisions, international customary law may set mandatory obligations. International customary law is usually not codified (not written) and may come into force if states have accepted and applied the respective obligation over a long period of time. For example, international customary law obliges a state in whose territory an activity is intended to take place which may have negative effects on a neighboring country to arrange for a consultation process with the potentially affected country.

Finally, there is so-called 'soft law,' which is not legally binding but may be politically highly relevant. Decisions of the organs of an international organization, such as the UN General Assembly, are considered to be soft law.

States only enter into international cooperation if there is a good reason and if international cooperation has an added value. As the ecological functions of soils, such as ensuring food supply, fighting climate change and the biodiversity crisis, are trans-boundary in nature, international cooperation is certainly reasonable and required to deal with these enormous challenges.

How international cooperation on sustainable soil management is organized will be elucidated in this subsection.

Sustainable development goals – the objective of a “land degradation neutral world”

In 2015, the UN General Assembly adopted the 2030 Agenda for Sustainable Development, which entails commitments for both developing and developed countries (United Nations, 2015). Several of the 17 SDGs and the 169 accompanying targets have implications for soil protection. All SDGs need to be considered in their complexity and jointly to achieve the ambitions of the 2030 Sustainable Development Agenda. Siloed thinking, meaning one SDG for itself, would not be sufficient, also with regard to sustainable soil management (Ehlers, 2016).

The SDG 15 and Target 15.3 are, however, the most pertinent ones as SDG 15 requests “to halt and reverse land degradation” and target 15.3 demands that states “... by 2030, combat desertification, and restore degraded land and soil, including land affected by desertification, drought and floods, and strive to achieve a land-degradation neutral world” (Boer and Hannam, 2017; Altvater et al., 2014).

It is important to mention that the objective of a land degradation neutral world (or 'land degradation neutrality' (LDN)) has been increasingly perceived as a kind of a leitmotiv of international and national soil governance (Boer et al., 2016; Bodle et al., 2020; Fowler and Hannam, 2019). Although the 2030 Agenda, including the SDGs, is not legally binding, it is politically important as it was endorsed by all states.

During COP 12 of the UNCCD, a definition of LDN was unanimously adopted:

Land degradation neutrality is a state whereby the amount and quality of land resources necessary to support ecosystem functions and services and enhance food security remain stable or increase within specified temporal and spatial scales and ecosystems.

(UNCCD, 2015)

Soil is an essential element of land, therefore the LDN objective is directly applicable to soils (Ginzky, 2017). The definition furthermore underlines that the “amount and quality” has to “remain stable or increase.” Thereby, it is stressed that the neutrality objective has to be thought of in both quantitative and qualitative terms. Moreover, as land and soil degradation cannot be completely avoided, restoration or rehabilitation must be actively undertaken to achieve the objective of 'neutrality,' expressed in the phrase “remain stable or increase” (Ehlers, 2016).

The UNCCD – with its entity aimed at the 'science-policy interface' – has developed the conceptual framework for understanding LDN and recommendations on the necessary measures to achieve it. This conceptual framework is intended to support states with the implementation of the LDN objective in their respective home countries. The conceptual framework is clear, concise and instructive and, in that sense, a very useful instrument.

The UNCCD's 'LDN response hierarchy' (UNCCD, 2017)⁷ entails three necessary categories of actions: avoid, reduce and reverse (Cowie et al., 2018). Avoid is aimed at preventing degradation; in other words, that no degradation occurs. The term reduce is aimed at actions to ensure that the negative effects of an activity on soils are minimized to the lowest level possible. Reverse includes measures to restore or to rehabilitate degradation processes. In the view of UNCCD, 'restoration' seeks to “re-establish the pre-existing biotic integrity” and 'rehabilitation' is intended to “reinstatement the ecosystem functionality with the focus on provision

⁷In addition, many other matters have to be clarified, defined and arranged, i.e. the following points: A baseline has to be defined, the status of soil/land have to be assessed, indicators for the assessment of the status, of land degradation and of restoration/rehabilitation actions as well as monitoring requirements have to be defined. For further information, see Ehlers, 2016, Minelli et al., 2016 and Cowie 2018.

of goods and services" (Cowie et al., 2018). Finally, pursuant to the conceptual framework, "a pro-active focus on planning" needs to be in place by which "anticipated losses" should be counterbalanced by "planned gains" (Cowie et al., 2018).

These four categories of required measures need to be taken into account when implementing LDN nationally. They could also serve as evaluation criteria as to whether and to what extent LDN is already implemented (Ginzky, 2020).

Treaty provisions

There is currently no international treaty specifically dealing with soils (Ginzky, 2016; Boer et al., 2016; Bodle et al., 2020). Thus, no international treaty sets a general framework for sustainable soil management or acts like an anchor for this topic. In fact, the topic is addressed by various international treaties from different angles. Most belong to international conventions which were developed and finally concluded in the context of the first Rio Conference on Environment and Development (also known as the Earth Summit) in 1992, shortly after the dissolution of the former Soviet Union. That significant change in the political landscape followed by a relaxation of international tensions worldwide provided a window of opportunity for international cooperation.

The UN Convention to Combat Desertification (UNCCD),⁸ the Convention on Biological Diversity (CBD)⁹ and the UN Framework Convention on Climate Change (UNFCCC) were the three conventions resulting from the Rio Conference, all of which contain provisions relevant to the sustainable management of soils. The three treaties apply almost universally, meaning to almost all states as signatories, and entail legally binding provisions that have to be complied with by the State Parties.¹⁰ However, each of the three treaties has a specific substantive focus and is thus per se limited with regard to sustainable soil management. Moreover, it could be said that no treaty contains soil specific requirements. Soils are therefore dealt with more as a side-effect in these three treaties. In the following, these three regimes are analyzed concerning their provisions on sustainable soil management.

The UNCCD is the most relevant regime for the management of soils as it expressively refers to 'land.' However, the UNCCD, formally taken, is only applicable to so-called 'dry-lands.' Dry-lands, pursuant to the legal definition of the UNCCD, occupy about 40% of the Earth's terrestrial surface (Boer and Hannam, 2003). Thus, the UNCCD is formally only applicable to less than half of the land globally. Moreover, the UNCCD does not contain any soil-specific actions. Countries affected by land degradation are obliged to implement National Action Programs (NAP) and report back to the UNCCD on their individual NAP (Hannam and Boer, 2002). Thus, a country's NAP could entail measures specifically addressing sustainable soil management.

As explored above, in 2015 the UNCCD established itself as the leading regime for the implementation of a 'land degradation neutral world' by various decisions taken by the Conference of the Parties (Boer et al., 2016). Furthermore, the UNCCD has launched the voluntary target setting program for Land Degradation Neutrality (LDN) (Mastrojeni, 2018). More than one hundred states have joined.¹¹

The scope of application of the CBD could, in general, encompass all soil functions (Ginzky, 2016; Hannam and Boer, 2002). It would allow for holistic regulation of sustainable soil management. However, the CBD does not currently foresee specific measures with regard to soils. There are only a few programs that might have positive benefits for soils, like that on agricultural biodiversity (Wolff and Kaphengst, 2016).

The prime focus of the UNFCCC is climate change issues. With regard to soils, the UNFCCC provisions on accounting, maintaining and restoring sinks and reservoirs provide a general legal framework for action, which is relevant to soils as a carbon sink. However, the UNFCCC does not establish specific requirements concerning the management of soils (Boer et al., 2016; Streck and Gay, 2016; Bodle et al., 2020). In 2015, the Paris Agreement was signed and has set new and more ambitious quantitative targets, which aim to hold the increase of global average temperature to "well below 2 degrees" and at best at 1.5 degrees Celsius (see Article 2.1 (a) Paris Agreement). The Paris Agreement was seen as a major step forward in international climate governance, both with regard to the more ambitious target and the introduction of a new regulatory concept (Boer et al., 2016). The latter required State Parties to submit "Nationally Determined Contributions" and for those to be evaluated 5 years later, i.e., 2021, thereby establishing a control mechanism over their actions towards their commitments.

The Paris Agreement, however, did not establish specific soil-related obligations. A major challenge for the implementation of the Paris Agreement has been the accounting of the Nationally Determined Contributions (Paris Agreement, Paragraph 31.3). To this end, a working group has been established, which was also tasked with determining a state's requirements for soil and land management (Fee, 2018).

The three most relevant international treaties, namely the UNCCD, the CBD and the UNFCCC/Paris Agreement, do not entail, either alone or jointly, a complete regulatory concept for sustainable soil management. Furthermore, the UNCCD, the CBD and the UNFCCC do not include soil-specific provisions. Given the cross-cutting nature and the particular challenges in governing soils – inter alia, the huge variety of soils, the interface with tenure rights, the potential for economically conflicting interests – the actual level or even indirect effects of international regulations on soil conservation at the local level is thus very limited. As these treaties and regimes act somewhat according to their own logic, there is no overarching soil regulatory regime that sets a general framework or coordinates the various actions.

Global soil partnership – Food and Agriculture Organization

The Food and Agriculture Organization (FAO), together with the Global Soil Partnership, is another important actor in the field of sustainable soil management. In December 2012, the FAO established the Global Soil Partnership (GSP) with regional branches on all continents to promote sustainable soil management and to enable international and regional cooperation. The GSP has been very instrumental, in particular, in strengthening regional cooperation, collection of soil-related information – inter alia, through the new Technical Panel on Soils,¹² the exchange of information and knowledge and finally on awareness-raising at all levels.

Jointly, the FAO and GSP promote scientific knowledge on the various soil threats and drivers. Several large international workshops have been held on relevant soil topics, such as soil pollution, erosion and biodiversity.¹³ Based on these workshops, informative reports have been published. In addition, myriad other information on sustainable soil management has been provided. Thus, the FAO has clearly extended its focus from agricultural soils to a more comprehensive soil-related perspective (Bodde et al., 2020).

Right to food

Food security is one of the essential services that soils provide to society. The eradication of hunger and poverty are of keen interest primarily in developing countries. Sustainable soil management and the enforcement of human rights are thus closely linked. For many years, international law has recognized the human right to food. It is understood as an element of the right to life according to International Covenant on Civil and Political Rights.¹⁴ Furthermore, the human right to food is expressly mentioned in the International Covenant on Economic, Social and Cultural Rights (Article 11).¹⁵ Both international treaties have been ratified by about 170 states and thus almost universally applicable (Elver, 2018; Ruppel, 2021). Access to land and natural resources is often a precondition to ensuring food security – particularly in developing countries (Poderatti, 2022; Tamasang, 2022). Thus, soil governance is not only an environmental challenge, but needs to be considered with regard to its human rights dimensions, with a particular focus on the human right to food.

Sustainable soil management as a common concern of humankind

There is an ongoing debate about whether sustainable soil management is to be recognized as a common concern of humankind (Boer, 2014). The concept of ‘common concern of humankind’ is a principle of international law, which, if applicable to something, commits states to more intensified attention to it and increased international cooperation (Cottier et al., 2014; Bowling et al., 2016; Ginzky, 2017). The concept of common concern of humankind primarily refers to global problems or challenges which “inevitably transcend the boundaries of single states and require collective action in response.”¹⁶ Several international treaties have explicitly stated that a specific challenge, for example to fight climate change (as stated in the UNFCCC), is a common concern of humankind.

Sustainable soil management deals with social and/or ecological services which are transboundary in nature and challenges requiring cooperation between states, e.g. poverty eradication, hunger prevention, climate mitigation and adaptation and reversing biodiversity decline, therefore, it could be seen as a common concern of humankind. Several international joint statements, such as the outcome document of the Rio + 20 Conference “The Future – we want”, emphasize this assumption. However, as there is no international soil treaty, a legally binding expression that this principle should apply is yet to come (Ginzky, 2017).

Recommendation and outlook

Although there is no standalone international treaty on sustainable soil management, the last few years have seen considerable momentum to regulate and increase sustainable soil management better through international cooperation. Most importantly, the global community officially recognized ‘land degradation’ as a joint challenge in the Rio + 20 outcome document “The future – we want” and through the objective of land degradation neutrality in target 15.3 of Sustainable Development Goal 15.

The UNCCD has been very supportive in this context by establishing itself as the international lead organization, unanimously adopting the definition of LDN and creating the voluntary target setting program. The FAO and GSP primarily support the promotion of sustainable soil management by providing scientific information.

It is debatable whether to negotiate and finally adopt a new treaty on sustainable soil management would be a clever strategy given the resources required and the time needed. Nevertheless, the urgency of appropriate, targeted measures must be taken into account, inter alia, due to the unacceptable realities of extreme hunger and poverty as well as the effects of the ongoing climate change and biodiversity crises affected by and/or linked to unsustainable soil management. A proposal has been submitted to apply the regulatory framework of the Paris Agreement to soils (Fowler and Hannam, 2019; Bodde et al., 2020), which was based on the agreement of an overarching objective: State Parties should be obliged to contribute to the extent that is nationally possible, but

¹⁶Shelton (2009), p. 83.

with reporting and re-assessment responsibilities embraced. It would certainly be a step forward if such a concept could be agreed upon quickly.

It seems promising that there is now better and intensified cooperation between the UNCCD and FAO/GSP, as well as perhaps the UNFCCC. A particular focus of these cooperative endeavors, however, should be the development of appropriate measures on how sustainable soil management could be achieved locally in the light of various drivers: agriculture, industry, land take and sealing due to housing and infrastructure, among others. Another essential aspect is the provision of sufficient financial resources and technical support to developing countries.

Location-specific soil governance is crucial to deal with the challenges. At the international level, general recommendations on appropriate concepts and instruments should be developed to inform and assist national policy makers.

National and regional level

The previous section has shown that soil governance internationally could mainly serve two purposes: first, to create, maintain and enhance cooperation amongst states with regard to this common challenge of soil protection, and second, to set incentives on states to engage nationally. These 'incentives' at the international level could be very different, including legal obligations, the provision of funding or development aid, capacity building or economic benefits.

Sustainable soil management needs to be initiated and implemented with specific regard to location as the challenges have to be addressed and resolved locally. Soils are bound to land, which is immobile and therefore contained within the boundaries of a sovereign nation. Thus, soil governance at national or regional level is crucial to work towards sustainable soil management. Soil governance at the regional level means the cooperation of states within a region, such as the Member States within the European Union (Raffelsiefen and Straßburger, 2016; Heuser, 2022) or African countries within the African Union (Kibugi, 2017, 2020), which could consist of shared agendas, programs, policies and legal provisions. The institutional settings and involvement of civil society are also of importance.

There has been considerable interest in soil governance at national level in recent years. For example, Germany has initiated a process to revise its soil governance completely in order to adapt, in particular, to the climate change and biodiversity crises and to other current needs.¹⁷ Its aim is to draft a regulatory regime which is robust enough to tackle the 'real' challenges. The EU Commission published its new Soil Strategy in November 2021, which sets the objective of achieving 'healthy soils' throughout the European Union by 2050. To this end, a draft 'soil health law' should be submitted by the European Commission in early 2023.¹⁸ Mexico has started a process on the 'gobernanza del suelo,' translated as governance of the soil (Ortiz Garcia et al., 2022). A similar debate was initiated by the Asian Research Institute for Environmental Law for the South-East Pacific Region, aimed at informing on soil governance of countries in the region.¹⁹ And the Pan-African Parliament is in the process of drafting model legislation on sustainable soil management, which, according to the procedures of the Pan-African Parliament, would then be recommended to all national parliaments in Africa for consideration and obviously necessary adaptation to the national context and refinement (Ruppel and Ginzky, 2021).

Soils are essential to so many important aspects of our lives, therefore it could be expected that endeavors to improve soil governance at national and regional levels will arise in many if not almost all places. Thus, an intense debate on good soil governance is important and must be moderated and extended widely.

It is not possible to provide information on the current soil governance in all states. There are other sources for this kind of information such as FAO SoILEX. The following subsections are intended to provide insight into to what is needed for 'good' soil governance at national and regional levels. To this end, it should be elucidated which core regulatory elements of good soil governance, in the sense of legal mechanisms and instruments, are needed. Second, some light should be shed on the importance of the often-neglected issue of tenure rights. Third, the importance of appropriate institutional settings should be discussed to implement and enforce effectively soil-related legal provisions. In addition, some short observations should be made with regard to the interface of soil governance and cultural and ethical aspects, followed by an excursus on current German soil governance as a concrete example.

Core elements of good soil governance at the national level

The following overview on the core elements of good soil governance are not meant to be comprehensive; the chapter provides a general compilation of the most relevant aspects.

Soil as natural resource which provides several crucial social and ecological services

Sustainable soil management faces cross-cutting challenges. Thus, soils have to be managed sustainably with regard to all uses, threats and drivers. To cope with these challenges, it is instrumental to mention three objectives that should be upheld for each national legislation. It is important that the objectives are understood as legally binding: First, each legislation should acknowledge

¹⁷See the "contract" of the new German Government: <https://www.bundesregierung.de/breg-de/aktuelles/koalitionsvertrag-2021-1990800>.

¹⁸https://ec.europa.eu/environment/publications/eu-soil-strategy-2030_en.

¹⁹<https://www.umweltbundesamt.de/en/webinar-soil-governance-southeast-asia-in-focus>.

that soils are a natural resource, which needs to be protected and used in a sustainable manner to stress that soils which are owned privately nevertheless bear value that is of interest to all. Thereby, it would be clarified that owners of land and soils do not have an unconditional right to exploit the owned resource (Ruppel and Ginzky, 2021).

Second, each legislation should stipulate as a legally binding objective that the social and ecological services of soils are to be maintained and at best enhanced. Such an objective would also oblige landowners to manage their land and soil sustainably, respecting the services provided by the soils. Moreover, such an objective would also bind the governmental entities. Third, to abide by the international agreements, it would also help and be effective to stipulate land degradation neutrality as a legally binding objective of the national soil legislation. Thereby, a requirement would be established on the implementation of this objective by, *inter alia*, the LDN response hierarchy with the four elements of avoid, reduce and reverse as well as precautionary planning as foreseen in the UNCCD LDN conceptual framework (Bodle and Stockhaus, 2019).

Regulatory concept: Framework law and sectoral provisions

A few states only have their own act on soil issues (Peake and Robb, 2022). Moreover, these specific acts often do not address all soil aspects comprehensively. For example, the German Federal Act on Soils primarily entails provision concerning the identification, assessment and rehabilitation of brownfield sites (areas of land previously developed rather than unconverted greenfield sites). In addition, several legal studies have concluded that a legislative framework on sustainable soil management is recommendable because it could determine the most essential aspects of good soil governance, such as the objective and main operative provisions. At the same time, however, it would need to leave regulation of the specificities of certain soil threats, such as the handling of pesticides, urbanization processes, building of infrastructure, to specific provisions in other pieces of legislation specific to certain sectors (with regard to the envisaged model law in Africa – Ruppel and Ginzky, 2021).

What could or should such a framework law entail? It seems to be reasonable that it should stipulate the three objectives of soils being a natural resource, maintenance of the social and ecological services of soils and implementation and enforcement of the objective of land degradation neutrality. Furthermore, it should establish a procedure that would allow for *ex ante* control of activities that may be detrimental to soils. The applicant for such activities would need to be obliged to at least minimize or at best completely prevent probable negative effects to the soil. To have the necessary information available to propose an informed decision as to whether the activity may proceed, the framework law should require an environmental impact assessment to be conducted for such activities. And moreover, an obligation should be included that the applicant and operator of such an activity that causes negative effects on soils which could not be avoided must compensate by enhancing soil conditions in other locations. Thereby, the objective of land degradation neutrality as the balance of ongoing land and soil degradation and rehabilitation or restoration projects (Ehlers, 2016) could be realized (Bodle, 2017).

Complementary provision in other pieces of legislation

As mentioned above, there are many drivers of soil degradation and various soil threats. For example, the ongoing land take by housing or transportation infrastructure development, which may result in an extreme form of land and soil degradation called sealing; unsustainable agricultural practices, e.g. inappropriate use of peatlands which sequester carbon and are therefore important for climate mitigation; contamination of soils at brownfield sites or by new ubiquitously introduced and often persistent hazardous substances or plastics; as well as the role of soils for climate adaptation particularly in urban areas. These different drivers, threats and uses of soil require specific regulatory approaches. It is not possible to outline all of these regulations in the framework law concerning sustainable soil management. Thus, specific pieces of legislation will need to supplement it and flesh out these different regulatory approaches.

Nevertheless, the framework law should set the three overarching objectives towards which all these sectoral provisions need to be directed in order to manage effectively, coherently and concisely all uses of soils and all drivers and threats.

Relevance of soil data and information

Another important aspect of good environmental governance is the availability of data and information. Without a sufficient level of information, effective governance is not possible. The selection, assessment, documentation and distribution of data and information are additional aspects that should be dealt with in the framework law with its overarching nature (Ginzky, 2022).

There are several categories of necessary soil data and information. Information is necessary on the condition of soils in a specific location, the potential services a specific soil plot could provide, its vulnerability and its current uses. In addition, information is also needed on the potential effects of specific activities, such as the impact of pesticides, of (partial) sealing or of the introduction of contaminants. Finally, information on the techniques used also would be essential, including measures to reduce the negative effects.

To have such information available, appropriate scientific entities must be established in all countries. They should gather, evaluate and assess soil data and information. Furthermore, the information needs to be made available to policy makers and other users (private sector, farmers).

To create these scientific entities, to establish a strong science–policy interface and to reach out to civil society is a long-term task, but nevertheless, it is indispensable. The legislative basis for the scientific entity and for the collection, management and security of soil data and information should also be provided by the framework law (Ginzky and Ruppel, 2021).

Specified requirements for all soil uses in a legally binding form

Many research studies have shown that the success of soil governance in practice depends considerably on legally binding standards for the various soil threats, inter alia, compaction, erosion, soil sealing, loss of carbon and biodiversity, salinization, water scarcity, flooding (Ginzky, 2022; Ginzky and Ruppel, 2021). Standards are meant to set conditions for certain activities. They should entail standards on environmental quality (results-based) or on the design of the techniques applied (practice-based). Thereby, it should be determined which and at what level of negative effects on the environment, in our case specifically on soils, are acceptable. In other words, what kind of use is permitted legally and what is prohibited. For example, what amount of fertilizer may be applied, or not only what kind of chemicals may be released from industrial facilities but also what level of residue is acceptable in the soil?

These standards need to be legally binding to bind both the land/soil user and commit the competent governmental entities to uphold that standard. Legally binding standards would then work towards two ends: First, the user would know what is legally permissible. Second, the competent authorities would be instructed as to what needs to be implemented and enforced; not vague obligations and ambitions, but very clear and specific requirements.

Experience shows that the development and adoption of such standards is very demanding and time- and resource-consuming. As legally binding standards determine what is permissible and what is not, the adoption of such standards is in most cases very controversial. Thus, it helps that the FAO has published guidelines on various soil threats; for example, on pollution, erosion and biodiversity, which could be used as a basis for the national decision-making process or at least as a kind of anchor for all competent authorities that are in charge of implementing the national provisions.²⁰

Procedural rights and courts

Finally, stakeholders and civil society need to become sufficiently involved. The commonly accepted governance instruments, e.g. access to environmental information, public participation and access to justice, need to be implemented with regard to activities that are relevant to soils. Respective provisions could be foreseen in either sectoral provisions or in the framework law mentioned above.

In a few counties, such as Kenya (Kameri-Mbote, 2021), specific courts have been established to make judgments on environmental and land issues. Such an approach could serve three needs. First, to increase the level of judges' legal knowledge about how the law relates to issues of soil use and protection. Second, to emphasize the importance of these challenges in the national context. Third, to foster access to justice for those seeking redress due to unsustainable soil management.

Tenure rights

Clarity on land tenure is crucial for sustainable soil management because management responsibility is often linked to tenure. In other words, if it is not clear who owns or has access to a plot of land and the soil below, there is no clarity as to who is in charge of ensuring sustainable handling of it. In addition, there is a social dimension of land tenure as access to land is extremely important in many states where people depend on agriculture for their livelihoods and subsistence. As land has become a commodity of interest due to the food crisis at the beginning of the century, the acquisition of land for current and future uses by often powerful national or foreign investors has placed local communities under additional pressure.

In some countries and regions, the lack of clarity over tenure is caused by the conflict of so-called modern law and traditional concepts of land ownership. African countries are relevant case studies in this context (Ruppel and Ginzky, 2021; Tamasang, 2022; Towela Sambo, 2021). Foreign or even national investors may benefit from such 'obscurity' to strengthen their interests, particularly in weak or corrupt land rights systems.

Lack of legal clarity on tenure is often a strong impediment to sustainable soil management, particularly in developing countries as many examples have shown. In cases of legal non-clarity, people are not clear about their responsibilities or duties and there is less incentive to treat the land well because that individual does not know how long they will have access to it, so short-term exploitation may be prioritized. In addition, strong investors may misuse this legal lack of clarity to circumvent the proper registration process or stake a claim in the knowledge that they will win support rather than a diffuse number of less powerful interested holders, for instance (Tamasang, 2022; Ginzky and Ruppel, 2021; Ginzky et al., 2021a).

Clarification of tenure rights would thus serve several purposes. First, it could support poverty eradication. Second, it is one important instrument to control national or foreign investors by avoiding illegitimate land acquisitions. Simply, clarity on land tenure is the basis for more environmental responsibility, which would be particularly useful to strengthen sustainable soil management.

Importance of administrative arrangements – the case of implementation and enforcement

Soil governance largely depends on effective institutional settings and arrangements for its implementation and enforcement. This aspect is often neglected because of its technical nature. Nevertheless, as experience has shown, brilliant substantive provisions are only ink on the paper without effective implementation and enforcement (Ginzky et al., 2021a).

There are mainly four administrative tasks for governmental entities to effect soil governance. First, the gathering of soil information, which also requires inter alia a lot of environmental monitoring on the ground, assessment of the data gathered

²⁰<https://www.fao.org/soils-portal/en/>

and its later dissemination to policy makers and civil society. Second, legally binding standards need to be developed and adopted. Third, potentially detrimental activities must be subject to an *ex-ante* control mechanism by governmental entities. Fourth, compliance with substantial provisions needs to be monitored and, in the case of non-compliance, enforced (Ginzky, 2022).

These tasks have to be attributed to specific governmental entities to clarify who is in charge and to avoid overlaps of responsibilities and lack of coordination. To this end, the roles and responsibilities of the various ministries and competent authorities need to be determined clearly by legal provisions.

Although implementation and enforcement seem to be primarily a technical issue, the complexity of the challenge to establish an effective institutional setting should not be underestimated. Responsibilities accompany reputation, influence and power, therefore, the decision-making process could be politically very controversial amongst the entities involved.

Soils, culture and ethics

Nature and landscape trigger emotions, perceptions of the interlinkages of nature and human beings and thus traditions, culture and ethical values (Heuser, 2017). The Catholic religion has a specific understanding of nature and soils, inter alia, regarding humans as double-being: 'earthbound' and spiritual (Voigt, 2019). Similarly, for other world religions such as Buddhism or Hinduism.

It is important to recognize that the magnitude and diversity of cultural or ethical perceptions is somewhat endless (Shikongo, 2016). Cameroon alone assembles more than 270 culturally different entities with almost the same number of languages. Thus, it is called 'l'Afrique en miniature' (Tamasang, 2021). A North American indigenous perspective on Mother Earth asks: "who is governing who?" (Poitras, 2022).

These cultural or ethical perceptions at local, regional or national levels should be taken into account when drafting instruments and concepts for soil governance. It is important to consider different cultural or ethical understandings of societal groups respectfully, such as local communities, in attempting to understand how soils are used, by whom, for what purpose, etc. Such a respectful approach is also reasonable from the point of view of law enforcement as people are more willing to comply with regulations if their perceptions have been referred to in the legislation.

Excursus one: Soil governance in Germany

This subsection gives example of national soil governance (Peake and Robb, 2022), which shows how complicated it is to achieve comprehensive and effective soil governance.

Industrialization in Germany during the middle of the 19th Century caused severe contamination of soil and the local groundwater bodies, leading to about 425,000 brownfield sites. Calculations of the costs for rehabilitation exceed more than 500 billion Euro (Ginzky, 2021). A second driver is the threat to soil linked to ongoing industrial activities. Urbanization and related necessary infrastructure, such as streets and railways, are a third factor (Schlacke and Jürschik, 2018). The land take in Germany of about 58 ha per day is still unsustainably high; about half of which is ultimately sealed. The fourth threat to soil is linked to the continuous intensification of agriculture. Climate change is the last (but probably not least) driver of soil impacts in Germany, which has not yet been thoroughly assessed scientifically.

Germany is one of the few states that has a specific Soil Protection Act (SPA).²¹ The German Soil Protection Act was adopted in 1998 and therefore 2018 marked its 20th anniversary. Paragraph 1 of the German Soil Protection Act stipulates that soil functions must be maintained sustainably and or rehabilitated, and that to this end both reactive and precautionary measures have to be taken. The overall objective of the law is broad enough to encompass all drivers of soil degradation and all soil threats. Moreover, the law addresses soil as a natural resource and stresses the need to foster its ecosystem services (functions is another term) of soils.

However, the core operative provisions of this act focus on the regulation of and how to clean up contaminated industrial sites, including landfill sites (§§ 4 and 10 SPA). The Soil Protection Act's focus is thus mainly on the rehabilitation of soils contaminated by industrial uses.

The law also outlines some provisions with regard to 'good agricultural practices' (§ 17 SPA). However, these provisions are not mandatory and are very vague. They relate to the requirement that agricultural practice should consider the site-specific conditions of a plot of soil. Almost no legally binding standards are in place with regard to these good agricultural practices, and the obligation to comply does not have a stringent behavior-altering effect.

Germany is a very industrialized country, therefore, there is also a need to avoid future contamination of the soil by ongoing or future industrial activities. Thus, the German Act on Emission Control²² requires *ex-ante* permission for industrial sites. The permission to build industrial sites may only be granted if detrimental effects on the environment, including soils, are prevented. With regard to the maintenance of soil functions, before production starts the operator is required to examine and document the status of soils on the industrial site. After closure of the site, if significant negative effects have been caused the operator is required to rehabilitate the site to the 'original' status (§ 5 BImSchG). The provision clearly creates an incentive to avoid negative effects on soils caused by new industrial uses.

²¹Gesetz zum Schutz vor schädlichen Bodenveränderungen und zur Sanierung von Altlasten (Bundes-Bodenschutzgesetz - BBodSchG), 17.3.1998.

²²Gesetz zum Schutz vor schädlichen Umwelteinwirkungen durch Luftverunreinigungen, Geräusche, Erschütterungen und ähnliche Vorgänge (BImSchG), 15.3.1974.

Negative effects on soils by urbanization are dealt with in a specific piece of legislation. The German law on town planning and buildings²³ requires that soils should be managed economically and carefully. The act also demands town planning processes be structured so that the various concerns, i.e. need for accommodation and infrastructure, space for industrial uses, protection of the environment, social security, etc., must be taken into account and potential conflicts between them be settled. The act stipulates that if a town planning decision causes negative effects on nature, including soils, these negative effects have to be compensated for. This provision is of great importance for nature conservation, although it also has some drawbacks (Bodle et al., 2020). Concerning soils, the provision cannot be thoroughly implemented because important information is lacking on the condition of soils throughout Germany and no binding standards have been adopted yet.

Agriculture may be the cause of several soil threats. Contamination could result from the input of manure, fertilizer or pesticides. For all these categories of substances, specific pieces of legislation are in place in Germany, setting limits for emissions, uses or environmental quality standards (Möckel et al., 2014). For almost all other, not substance related, soil threats caused by agriculture, such as soil erosion, decline in organic matter, decline in biodiversity or salinization, no legally binding standards have been adopted.

Land take, or infrastructure such as streets, airports or railways, are dealt with by further legislation. Infrastructure measures usually also require *ex-ante* permission. The competent authority must, before granting the permission, consider all relevant concerns including soil aspects. Similar to urbanization, it is mandatory to offset detrimental effects on nature caused by infrastructure developments. However, there are the drawbacks mentioned above.

The Soil Protection Act stipulates precautionary limits with regard to contamination which are legally binding. These limits have to be considered when other sectoral provisions are implemented and effects on soils are to be managed. With regard to soil contamination, the German Soil Protection Act could therefore be regarded as a kind of a framework regulation.

In summary, it has been shown that German soil governance addresses the various drivers of soil degradation and threats by a combination of the overarching Soil Protection Act and several sectoral provisions. Legally binding standards, however, have been adopted only with regard to soil contamination. For most other soil threats, legally binding requirements, for example, on compaction or erosion are missing. Consequently, law enforcement is weak with regard to this (Ginzky et al., 2019). The division of soil-related provisions over several acts is not a problem in itself, but what weakens the legal implementation or enforcement is if there are no legally binding standards to which users may be held, such as those of environmental quality (Ginzky et al., 2019).

Of note: Land degradation neutrality has not yet been included as an objective in German soil governance (Bodle et al., 2019).

Excursus two: Methodological observations

It is a complex and demanding task to either draft or amend soil legislation. To be able to submit well substantiated proposals as a legislator for political discussion, it is essential to apply a convincing methodology. The following subsection provides some general considerations on how such a task could be approached. This methodological approach has been used to inform existing legislation at the national level (Ruppel and Ginzky, 2021) and for the various country reports in the volumes of the *International Yearbook of Soil Law and Policy*.

The methodology encompasses four main steps. First, a description of the historical, societal, economic and political conditions and circumstances is required. This could be used primarily to inform foreigners. Nevertheless, it could also be instrumental for national discussion to establish a common 'starting point.' Second, it is appropriate for determining what are the main soil threats and drivers in the respective country. This may differ significantly. The outcome of the analysis should be used to decide on the focus of the national soil legislative process.

Third, if the focus is on amendment of an existing law, an analysis of the legal provisions is needed. This should refer mainly to the country's core threats and drivers. Technically speaking, the analysis should include constitutional provisions, environmental laws, including subsidiary environmental standards and guidelines, tenure rights, as well as international and regional treaties and agreements. Finally, the institutional, organizational and financial settings should be analyzed, including aspects such as data gathering and distribution, administration, roles, communities, local chiefs to determine the strengths and weaknesses of current arrangements and to identify room for improvement. This is of eminent importance because implementation and enforcement are key (Ginzky, 2022).

With regard to the last two steps of the investigation, it is advisable to investigate solutions that have been applied successfully in other national legislation. Considerable knowledge is available to this end. The *SoiLEX*, as described above, is a database that assembles information on most national legislation and is thus an indispensable tool in this context. In addition, each of the five volumes of the *International Yearbook of Soil Law and Policy* includes several legal analyses of national soil governance systems; in total more than 30 chapters which explain both the strengths and weaknesses. In addition, the comparative work for a model law on sustainable soil management in Africa (Ruppel and Ginzky, 2021) and the two anthologies on Indian (Desai, 2022) and African soil law (Yahyah et al., 2020) could be considered. Therefore, all this knowledge and expertise could and should be considered when drafting national legislation on sustainable soil management.

²³Baugesetzbuch (BauGB), 23.6.1960.

Transboundary trade and sustainable soil management

International trade on the one hand and food security and sustainable soil management on the other hand are closely interlinked, which is also addressed by the SDGs (Ehlers, 2016; Elver, 2018). Food security depends strongly on the sustainable management of soils because with water it is the essential natural resource to grow food, at least in most developing countries. Food security, therefore, could be regarded as a precondition to achieve sustainability in general (Ruppel, 2021).

International trade, on the one hand, could support the aim of food security by several mechanisms, such as the immediate supply of food but also with the supply of seeds, fertilizers or agricultural technical equipment (Ruppel, 2021). On the other hand, reality suggests that international trade could also have a huge destabilizing effect on food security in regions because of disruptions to supplies, growing unilateralism and competition over agricultural resources, including soil itself (Windfuhr, 2016). Moreover, international trade could and has been an instrument of geopolitics (Ruppel, 2021).

International trade in agricultural products needs to ensure that the sustainable management of soils in both exporting and importing countries is not impeded or even made impossible. To this end, two main objectives should be regarded as requirements to international trade in agricultural products. First, it should not lead to direct or indirect negative effects on soils. Second, international trade in raw agricultural products which are exported by a developing country should be combined with an obligation on the importing country (potentially or likely in the Global North) to support the development and establishment of processing facilities in the exporting country (potentially or likely in the Global South). This requirement would create more autonomy in those countries in the Global South, which is in accord with the spirit of the SDGs (Ankersmit and Partiti, 2020).

It needs to be highlighted that current international trade law is somewhat unclear with regard to the two objectives just mentioned. Basically, it is currently about enabling more trade, i.e. free trade (Ruppel, 2021). Environmental standards in relation to how they factor these into trade structures and processes need to be developed further to work towards better food security and to avoid repercussions for sustainable soil management in various locations throughout the world.

Nevertheless, to avoid negative and hindering effects on soils from international trade in agricultural products is another crucial challenge to allow for sustainable soil management locally, which needs to be further discussed.

Outlook

The twenties of this century will be the decade of transformation. This will be either by design or by disaster. Sustainable soil management will be one core element to achieve transformation by design with other crucial topics, such as energy efficiency, energy supply systems based on renewables, a circular economy and sustainable agriculture. Thus, one could state emphatically that this decade will be the decade of soils. Whether this is over-stated or not, to achieve sustainable management of soils is non-negotiable.

Sustainable soil management can only be achieved with good governance. There are other factors, such as awareness, knowledge, capacity building and economic instruments. The chapter first explained the complexity and importance of sustainable soil management and soil governance. In addition, the existing soil-related instruments at the international level have been outlined. Moreover, the most important core elements for good governance of sustainable soil management have been explained.

There is no alternative to success. Thus, there is a need to speed up, to cooperate, to exchange views, to experiment and to evaluate. Transformation is not a result, it is primarily a process (Lehndorff, 2021; Ginzky et al., 2021b). It is hoped that this chapter lays out a basis to inform and support all experts, stakeholders and interested people in their ambition to work towards a world in which sustainable management of soils is not only an aspiration, but a reality.

Abstract

Soils influence human well-being in manifold ways. However, their multifunctionality implies trade-offs. Moreover, soils are a scarce stock of natural capital. Many soil-based ecosystem services are collective goods, whose provision is affected by externalities of soil management. This chapter provides an economic perspective on soils' contributions to human well-being and the associated challenges in terms of public preferences, property rights regimes and policy. It offers an overview of key concepts such as soil-based ecosystem services, property rights and collective goods dilemmas, economic valuation as well as incentive-based policy instruments that help align soil management with public preferences and societal well-being.

Glossary

Collective good A good providing benefits that can be enjoyed by anyone and from whose enjoyment no-one can be excluded.

Externality Side effect of an economic activity (e.g. soil management) that affects third parties without their consent.

Incentive-based policy instruments Policy instruments that rely on shifting relative prices (e.g. taxes, offsets), rather than prohibiting or commanding specific actions (e.g. emission or technology standards).

Information asymmetry A situation among at least two interacting agents, in which one of the agents possesses more information relevant to their interaction than the other(s).

Institutions Conventions, norms and formally sanctioned rules of a society (e.g. laws, social norms, property rights).

Marginal value The value attached by people to an incremental change of one unit (quantity or quality) of a good or service.

Market failure A situation in which unregulated market activity leads to societally undesirable outcomes (e.g. due to externalities).

Opportunity costs Foregone benefits of alternative uses of a resource (e.g. the profit from agricultural yields foregone in the event of conserving a piece of land).

Relative scarcity A good is scarce if its intended uses exceed the available quantity. Scarcity is relative if the good can be substituted with respect to a given use.

Social dilemma A situation in which independent rational behavior of individuals leads to an inferior overall outcome as compared with a situation in which individual actions were coordinated.

Key points

- Soils provide multiple benefits to human well-being (soil-based ecosystem services).
- Soil management affects the provision of soil-related collective goods.
- Existing legal property right regimes obscure the public-good nature of soil-based ecosystem services.
- Economic valuation can help demonstrate the contributions of soils to human well-being and the trade-offs involved.
- Incentive-based policy instruments can help align soil management with public preferences.
- The design of effective and efficient incentive-based soil policy instruments is challenging.

Introduction

Soils influence human well-being in manifold ways, e.g. by storing carbon, absorbing, storing and filtering water, providing habitat for biodiversity as well as contributing to the production of biomass that can be used as food, feed, energy or materials (Baveye et al.,

2016; Dominati et al., 2010). These numerous benefits illustrate soils' multifunctionality. However, soils cannot be managed to maximize all their contributions to human well-being (soil functions or soil-based ecosystem services) simultaneously. Their multifunctionality implies trade-offs. In this sense, they can be considered an essentially scarce resource. Their scarcity is relative, as many of their functions can be substituted or replaced by man-made alternatives, although imperfectly – examples of such substitution are synthetic fertilization, water treatment facilities, flood protection infrastructure, irrigation systems etc. Given the relative scarcity of soils in their multifunctionality and their multiple contributions to human well-being, soils can and should be considered an economic good or, more precisely, a natural capital stock (Dominati et al., 2010). In this view, soil functions and, ultimately, soil-based ecosystem services are benefit streams derived from this stock of natural capital.

Further, while some of the ecosystem services provided by soils benefit predominantly those who own and/or manage the land where they are located, many soil-based ecosystem services provide wider benefits to society. These ecosystem services can be considered public or collective goods. Against this background, a person's private activity, e.g. biomass production, may have negative or positive impacts on a third person not directly involved in the activity, or on society at large. In the case that the person undertaking the action does not consider costs or benefits imposed on others, an uncompensated damage (or spill-over benefit) exists, i.e. a so-called 'externality.' It is the primary role of societal institutions (laws, rules, norms) to internalize them, meaning that measures are undertaken to take into account uncompensated damage or benefits (formally: align private costs/benefits and social costs/benefits). This internalization of externalities can be based on three approaches, depending on context:

- State intervention in the form of corrective taxes (or subsidies in the case of positive externalities).
- Direct negotiations among affected parties, with the aim for contractual internalization (well-defined property rights are required).
- Bottom-up establishment of collective institutions (norms, rules) by those affected (Ostrom, 1990).

The fact that soils exhibit collective good characteristics suggests that there is a need for policy intervention to correct market failure and underprovision of the soil-related collective goods that arise due to soil degradation. This chapter provides an economic perspective on soils' contributions to human well-being and the associated challenges in terms of public preferences, property rights regimes and the design of policy interventions that aim at internalization.

Soil-based ecosystem services

The importance of soils for human well-being can be highlighted and analyzed by means of the ecosystem service concept (Dominati et al., 2010). This concept aims to demonstrate the contributions of ecosystems to human well-being and the associated value humans place on ecosystems (TEEB, 2010). Although scientific interest in the concept has risen substantially since the millennium, so far there has been no clearly defined terminology or a standardized classification of ecosystem services. Ecosystem services are often defined as the indirect and direct contributions of ecosystems to human well-being (TEEB, 2010). The development of the Common International Classification of Ecosystem Services (CICES) is considered an important contribution to a common understanding and standardization (Haines-Young and Potschin, 2018). The CICES differentiates ecosystem services into three overarching categories: provisioning services (e.g. food, timber), regulating and maintenance services (e.g. climate regulation, flow regulation, soil formation) and cultural services (e.g. recreation, esthetic experiences). Within these three main categories, CICES version 5.1 distinguishes between 83 so-called classes of ecosystem services (Haines-Young and Potschin, 2018).

To illustrate the complex relationship between ecosystems and human well-being in the form of a 'production chain,' Haines-Young and Potschin (2010) developed the so-called cascade model (Fig. 1). This model assumes a stepwise relationship between the biophysical context, processes and structures created by living organisms and their potential to provide ecosystem services, and the socio-cultural and economic context associated with benefits and value to humans. Final ecosystem services, i.e. all services that contribute directly to human well-being, are the link between the ecosystem functions (including soil functions) on the one hand and benefits and values on the other hand. Thus, there is a need to distinguish between an ecosystem's potential to provide ecosystem services and the actual supply and demand for ecosystem services, which by definition cannot exist in isolation of human needs (Haines-Young and Potschin, 2010). While the standard version of the cascade model is characterized by a unidirectional flow, decision-making may influence the biophysical structure through pressures, e.g. unsustainable management of resources.

As discussed above, soils fulfil multiple functions (production of biomass, water storage and filtration, nutrient cycling, carbon storage and habitat provision), which form the basis for the provision of ecosystem services. While the ecosystem service concept could make the contributions of soils to human well-being and the impacts of soil management on the provision of ecosystem services visible, CICES does not explicitly specify soil-based ecosystem services (Haines-Young and Potschin, 2018). Thus, defining ecosystem services provided by soils remains challenging because ecosystem services are characterized by complex interactions, e.g. between below-ground and (natural and human-driven) above-ground processes. Therefore, identical soils may provide varying levels of ecosystem services under different management regimes; soil-based ecosystem services are the result of an interplay between inherent as well as manageable soil properties (Dominati et al., 2010) and human needs and preferences, which determine for which soil functions there is demand (making them soil-based ecosystem services). For instance, fertilizer input affects the amount of fiber and food production. In this context, Paul et al. (2021) distinguished between (i) *soil-related* ecosystem services, i.e.

Fig. 1 The ecosystem service cascade model. Own illustration adapted from Haines-Young R and Potschin M (2018) *Common International Classification of Ecosystem Services (CICES) V5.1: Guidance on the Application of the Revised Structure*; see also, Haines-Young R and Potschin M (2010) The links between biodiversity, ecosystem services and human well-being. In: Raffaelli DG and Frid CLJ. *Ecosystem Ecology: A New Synthesis*. Cambridge: Cambridge University Press, 110–139.

all services affected by soil properties, e.g. soil quality by weathering processes (here called soil-based ecosystem services), and (ii) ecosystem services *affected by agricultural management of soil*. Of the 83 ecosystem service classes included in CICES, 29 were identified as soil-related and 40 were classified as affected by soil management, while 23 classes were part of both subsets. Furthermore, reconciling the contributions of soils to human well-being with the CICES classification is hampered by CICES's dualistic conception of biotic ecosystem services, e.g. biomass provision or carbon storage, and abiotic ecosystem services, e.g. groundwater for drinking or control of liquid flows. Soil-related services are often relevant for both categories as they are linked in the interaction zone between pedosphere, hydrosphere, atmosphere and biosphere (Paul et al., 2021). Additionally, the linear relationship between soil functions and soil-based ecosystem services suggested by the cascade model does not necessarily hold. Thus, in the literature definitions of soil-based ecosystem services correspond to some extent to definitions of soil functions (Baveye et al., 2016), but most definitions of soil functions arguably do not have a sufficiently clear link to human well-being. For example, the soil function 'water storage' is highly relevant for the soil-based ecosystem service 'flood protection,' but in the absence of further factors (proximity to human settlements, rivers or streams as source of flooding etc.), the function will not become an ecosystem service.

Collective goods and property rights regimes

Many of the soil-based ecosystem services mentioned in the previous section are public or collective goods. This means that others cannot be excluded from enjoying the benefits of the provision of these ecosystem services. For instance, while increasing the organic carbon content in soils has numerous benefits to the land users themselves (e.g. in terms of soil moisture and productivity), carbon sequestration and storage in soils also removes greenhouse gases from the atmosphere, thus contributing to the provision of a global collective good (a stable climate) enjoyed by every person alive as well as (and especially) future generations. However, while the land user can reap the private benefits of soil management, outweighing the associated costs of management changes, this is not the case for collective goods. Here, the land user as provider of a collective good bears the entire cost of its provision, in particular the opportunity costs resulting from not being able to manage differently, but they cannot reap the benefits, unless some institution has been set up to remunerate them.

The challenge posed by soils in this context is that they are multifunctional, and the private-good and collective-good aspects cannot be easily separated. Building upon Lancaster's consumer theory (Lancaster, 1966), which posits that consumers are interested in the characteristics of a good (e.g. taste, size, color in the case of an apple) rather than in the good as such, soils can be considered a bundle of characteristics (soil functions and soil-based ecosystem services), which contribute to human well-being in different ways (Bartkowski et al., 2018).

This has profound consequences for the conflict between *de facto* and *de jure* property rights toward soils. While in legal terms, soils are part of 'land,' which can be owned privately and bought and sold in the market, *de facto*, many of the ecosystem services provided by them are collective goods that defy private ownership and marketability. Moreover, private and collective goods are not a binary category, but rather a spectrum. To analyze this spectrum and locate various soil-based ecosystem services within it, it is useful to distinguish a set of actions that can be executed toward any economic good (Schlager and Ostrom, 1992). These actions are:

- Access, i.e., the physical interaction with land/soils;
- Withdrawal, i.e., enjoyment of the 'fruits' provided by land/soils;
- Management, i.e., modifying and regulating land/soils and their properties;
- Exclusion, i.e., preventing others from access, withdrawal, and/or management;
- Alienation, i.e., transferring the land to another person or entity (by selling or giving away).

Different persons or entities can possess different *de facto* and *de jure* rights toward the same good, i.e. control different actions related to this good. For instance, while the tenant may possess the exclusive right to cultivate a piece of land for a contractually defined period (access, withdrawal, management, exclusion), the land owner retains the right to sell the property in question (alienation) (Bartkowski et al., 2018). The same intuition holds for various soil-based ecosystem services, as exemplarily shown in Fig. 2. In particular, almost everyone can enjoy the benefits of collective-good ecosystem services (e.g. climate regulation or biodiversity) and no-one can be effectively excluded from enjoying them. In the absence of societal institutions that will address this problem, the land user does not have reasons to bear the cost of managing the soil to provide those soil-based ecosystem services that exhibit collective good properties. The objectives of management will thus be restricted to a subset of ecosystem services that directly affects the interests and well-being of the land user, thus leading to a social dilemma or collective-goods problem.

It is impractical to assign distinct legal property rights to each soil-based ecosystem service, and to define the actions permitted for each affected individual, entity or group. However, given how legal property rights are commonly assigned (their object being simply the land), the observation that *de facto* property rights of third parties are also affected creates a rationale for state intervention in the form of institutions (policy instruments) that provide incentives to land users to align their management with the interests of the affected parties. Thus, the social dilemma can potentially be resolved. However, before this can be done, it is first necessary to determine who is affected and how they are affected, i.e. what are the public preferences for various soil-based ecosystem services.

Economic valuation of soil-based ecosystem services

The primary motive for economic valuation of the environment, e.g. of soils, is to demonstrate the importance of ecosystem services for human well-being and the value these have for society. The focus is particularly on those ecosystem services that are not traded on markets and therefore do not have prices (nonmarket valuation). Further, economic valuation allows for the expression of trade-offs and assessment of the impact of alternative actions on human welfare (TEEB, 2010). A heuristic to assess the aggregate value of benefits associated with soil-based ecosystem services is the so-called Total Economic Value (TEV) framework. 'Total' refers here to the aggregate of different economic, i.e. preference-based value types and categories (see Fig. 3) and should not be confused with the absolute value derived by an ecosystem service. Usually, economic valuation of ecosystem services captures marginal values, i.e. the value of a small incremental change in the quantity or quality of the ecosystem service, which depends on the relative scarcity of the ecosystem service and, thus, its current levels of provision. Higher marginal value is associated with increasing scarcity in ecosystem service supply – below a minimal threshold, sometimes called 'critical natural capital,' when the ecosystem service supply becomes non-substitutable and, thus, essential to human survival, economic valuation ceases to be meaningful (Farley, 2008). Therefore, the aim is not to estimate the absolute value derived from an ecosystem service, but the marginal value associated

with a change in the state of the world. For example, a decision on whether to re-wet a peatland area would be informed by the marginal changes in ecosystem service provision with respect to the various value categories of the TEV, described in the following.

The various value categories comprise two overarching types of value: 'certain-world values' and 'uncertain-world values.' Certain-world values are independent of the uncertainty regarding future states of the world, whereas uncertain-world values derive from the inherent uncertainty over future demand and supply of soil-based ecosystem services (Bartkowski et al., 2020). Certain-world values can be divided into 'use values' and 'non-use values.' As suggested by the name, use values refer to values derived from the use of environmental goods which may be 'direct' and 'consumptive' (e.g. biomass production), direct and 'non-consumptive' (e.g. recreational activities such as metal detecting) or 'indirect' or 'passive' (e.g. climate regulation through carbon storage). Direct use values are often, though not always, reflected in market transactions, whereas indirect use values generally are not. The concept of non-use values captures all values of ecosystems that either relate to altruism toward other humans (philanthropic value) or toward nature (existence value). Philanthropic value may refer to the satisfaction of knowing that future generations will have access to benefits from a given (bundle of) ecosystem services or an ecosystem (bequest value) or that other people currently living have access to such benefits (altruistic value). Satisfaction derived from the knowledge that an ecosystem or species simply exists is referred to as 'existence value.' Despite the fact that non-use values are associated with other humans or non-human entities, these types of value are usually understood in terms of individual preferences. In other words, individual measures of value are of relevance with respect to individual satisfaction, e.g. of knowing that soils will provide benefits for future generations. Turning to the notion of uncertain-world values, the associated values account for the temporal dimension of soils and the provision of soil-based ecosystem services. The so-called 'option value' is associated with the continued ability to respond to future preferences and demand, i.e. it focuses on the preservation of options to use soils in the future and to enjoy the potential benefits of soil-based ecosystem services. 'Insurance value' arises from soils' potential to reduce variance in soil-based ecosystem service supply, in particular with regard to disturbances, and thus to supply uncertainty. Both types of value are strongly linked to biodiversity (Bartkowski et al., 2020; Pascual et al., 2015).

A variety of valuation methods can be used to estimate the TEV of ecosystems or ecosystem services. The choice of method is highly context specific, and there are multiple conflicting factors to consider, including the firmness of the theoretical underpinning of a method, the cost of its application, the associated data demands, flexibility and comprehensiveness. The primary goal of each nonmarket valuation method is the inference of preference information from proxies, mostly information about choice behavior. Two common options are the elicitation of preferences for hypothetical scenarios with questionnaires ('stated preference methods') and observation of individual market behavior that can be linked to ecosystem services ('revealed preference methods'). Among stated preference methods, one may distinguish contingent valuation, which is based on a direct question about respondents'

willingness to pay for a hypothetical change in the provision of an ecosystem service, and discrete choice experiments, which are based on respondents choosing among scenarios that are characterized by variable attributes (e.g. soil-based ecosystem services). Revealed preference methods include the travel cost method (inference of the value of an ecosystem, a landscape etc. from expenditures people incur to visit them) and hedonic pricing (analysis of market data – e.g. real estate or land markets – where price variations can be partly explained by spatially explicit provision of ecosystem services). Stated preference methods are the most comprehensive and flexible, but rather effort- and cost-intensive. Furthermore, they are based on the analysis of hypothetical choices, which may be biased and not reflect how people would behave in the real world. Revealed preference methods reflect actual choice behavior, but they can only be applied to a limited subset of ecosystem services, require substantial amounts of data and assume that people are aware of the benefits they derive from ecosystems. In some cases, the data demands and costs associated with preference-based valuation methods may be prohibitive. In such cases, more crude yet easier to apply methods are sometimes used, such as those based on market prices of comparable goods ('market price-based method'), the costs of replacement, preservation or restoration of the ecosystem service in question ('cost-based methods') or the estimation of production functions that link the production of market goods to ecosystem inputs ('production function method').

In the context of soils, cost-based methods or market price proxies are applied most often to estimate the economic value of soil-based ecosystem services, instead of state-of-the-art preference-based valuation methods (Bartkowski et al., 2020). For instance, in a particularly comprehensive study, Dominati et al. (2014), use replacement costs and market price proxies to calculate the economic values of a range of soil-based ecosystem services (including food provision, flood protection, nutrient cycling and climate regulation). However, cost-based methods are problematic, as they do not provide information about preferences for collective goods, but merely give insights about costs of technical solutions. These costs may be an inadequate proxy for values if public preferences differ significantly. In addition, market prices can only be considered rough proxies because, as discussed above, most environmental goods are non-marketable or rather the associated marketed goods are not equivalent to the soil-based ecosystem services. Furthermore, existing economic valuation studies consider only a minor part of the range of soil-based ecosystem services discussed above. Primarily, economic values of climate regulation (carbon storage), decomposition (nutrient cycling) and (cost of) soil erosion have been investigated in the empirical literature. Thus, the potential of economic valuation to inform decision-making has not yet been fully realized. Hence, there is a need to consider the whole range of soil-based ecosystem services including trade-offs among them and for the application of state-of-the-art methods (Bartkowski et al., 2020).

Incentive-based instruments for soil protection

As discussed above, soils provide multiple ecosystem services that are valued by the public and exhibit collective good characteristics. The latter implies that their provision is unlikely to be ascertained by markets, given conventional legal property rights regimes. Rather, a corrective intervention by the state is required. However, the spatial heterogeneity of soils suggests that the required corrections in management will vary across locations; also, their effects may manifest at different spatial and temporal scales. Furthermore, the demand for ecosystem services not only depends on the local potential of soils to provide them, but also on the availability of substitutes (e.g. flood protection through infiltration and water storage in soils can be substituted by flood protection walls), the characteristics of the local population (e.g. in terms of income and wealth or attitudes) and the opportunity costs of managing for a given ecosystem service (for instance, in highly productive areas, the opportunity costs of extensification are high). Therefore, in most cases, a mix of different policy instruments will be required to address soil multifunctionality in heterogeneous landscapes (Bartkowski et al., 2021a). Relatively rigid policy instruments such as legal standards or zoning are unlikely to be efficient on their own and should at least be complemented by incentive-based instruments. In some cases, overly rigid policies (e.g. bans of particular practices) may even backfire – e.g., a glyphosate ban has been shown to entail increasing pressure on soils due to a shift to mechanical weed control (Böcker et al., 2020).

The main challenge in crafting effective and efficient policy instrument mixes is that soil protection and the provision of soil-based ecosystem services constitute a so-called principal–agent problem. Land users are the agents who are supposed to manage the land and soil in accordance with the requirements and incentives provided by the principal, i.e. the state or, more broadly speaking, society. However, this principal–agent relationship is hampered by information asymmetry between the state (represented by regulatory agencies) and land users. This asymmetry is especially relevant in cases where the effectiveness of management changes is likely to depend on land users' local, often tacit, knowledge including that about (opportunity) costs. Further, the regulatory agency has only imperfect capability to monitor the land user's compliance with requirements and regulations. Both types of information asymmetry impose two major challenges, which are called 'adverse selection' and 'moral hazard,' respectively. In the context of soil protection, adverse selection particularly refers to where soil-friendly management is taking place: where it is most effective (i.e. according to the interest of the principal) or where it is cheapest (i.e. according to the interest of the agent). Properly designed instruments help to avoid adverse selection and to incentivize the implementation of protection measures where they are most effective, e.g. by offering payments for measured improvements in soil condition, rather than simply for the adoption of specified practices (Bartkowski, 2021). In contrast to adverse selection, moral hazard becomes relevant after the contractual agreement (or, analogously, after introduction of binding management standards). The regulatory agency is then unable to monitor perfectly the compliance by the land user, who has an incentive to manage in a way that will maximize their profit, rather than in the agreed/mandated, soil-friendly manner. In this context, digitalization and remote sensing are increasingly important technologies that reduce the costs of monitoring of compliance (Ehlers et al., 2021).

A third major challenge related to information asymmetry is called 'additionality.' Ex ante, the regulatory agency usually does not know what the land user will do in the absence of incentives for soil protection. Given that the provision of incentives is costly for the agency, it is rational to provide them only if the land user would not have changed to soil-friendly management in their absence. Otherwise, the land user receives a windfall profit for an activity they would have undertaken anyway, and the scarce funds used to fund non-additional behavior cannot be used to finance the provision of collective goods elsewhere. However, the land user's future decisions are affected by many factors (Bartkowski and Bartke, 2018), and the counterfactual case of no incentives is difficult to grasp, especially for longer-term problems. In some cases, it may therefore be rational (from the point of view of the regulating agency) to provide incentives for non-additional behavior to prevent a return to the undesirable earlier behavior when circumstances change (e.g. when prices for relevant inputs or outputs change, making opportunity costs of soil protection higher).

These three major challenges should be considered when evaluating the effectiveness and efficiency of policy instruments, including incentive-based instruments. The latter include payments, taxes and (tradable) offsets. Each of these can be found in the context of soil protection: for instance, in agriculture, agri-environmental payments are a common instrument to align soil management with societal preferences (Bartkowski et al., 2021b); taxes have been used and discussed especially as a means to reduce pesticide use (Möhring et al., 2020); tradable offsets have been discussed and implemented intensively with respect to initiatives aiming to increase the soil organic carbon content as a strategy for climate change mitigation (negative emissions) (Thamo and Pannell, 2016).

Agri-environmental payments are the most widespread incentive-based instrument and a specific form of 'payments for ecosystem services.' Here, an important distinction is between action-based and result-based variants. In the case of action-based payments, the payment is not directly linked to the environmental outcome that is supposed to be enhanced or protected. For instance, rather than paying for changes in soil organic carbon, the regulatory agency may offer payments for the adoption of practices that are assumed to be beneficial in terms of carbon sequestration and storage (e.g. non-inversion tillage). In theory, this approach would only be efficient if the regulatory agency had perfect, spatially explicit, ex-ante knowledge about the effects of the regulated activity. In practice, action-based payments are quite common due to the relatively low requirements in terms of measurement and monitoring. Result-based payments are the theoretically preferable alternative in the face of information asymmetries between the regulatory agency and the land users (Burton and Schwarz, 2013). Here, the payments are issued for ex-post measured changes in the environmental good. This approach is more efficient than action-based payments, but it poses high demands in terms of measurement and monitoring. Furthermore, it implies greater risk for land users, as they cannot be certain that their actions will lead to the envisioned results, thus securing them compensation payments (Derissen and Quaas, 2013). Within the European Union's Common Agricultural Policy, one of the largest agricultural and agri-environmental policy frameworks worldwide, none of the few result-based payment schemes is related to soils. An alternative, hybrid approach consists in offering payments on the basis of model predictions regarding the spatially explicit effects of management changes (Bartkowski et al., 2021b). A similar approach has already been tried out in the context of private soil carbon offset schemes (TerraCarbon, Indigo Ag, 2020) as a lower-cost alternative to regular, expensive measurements of changes in soil organic carbon. In the future, further developments in remote sensing technologies could also help address the challenge of prohibitive measurement/monitoring costs (Ehlers et al., 2021).

Taxes are the opposite of payments and have been used less intensively in the context of soil protection, mainly due to the difficulties of monitoring that is required for effective environmental taxes. They are primarily relevant when it comes to making problematic inputs (e.g. synthetic pesticides) more expensive (Möhring et al., 2020). In the context of soils, a slightly more widespread approach has been tradeable offsets. These have been used mainly in the context of nonpoint-source pollution such as nitrate (Stephenson and Shabman, 2017) and in the context of soil carbon (Thamo and Pannell, 2016). However, the former is associated with rather high transaction costs (i.e. costs of setting up schemes, monitoring, organizing a trade market etc.) and its effectiveness has been questioned (Stephenson and Shabman, 2017), while the latter has faced a major obstacle in the need to establish permanence (Thamo and Pannell, 2016), which is required for a real climate effect of soil carbon storage.

Overall, the design of effective and efficient soil protection policy mixes is quite challenging and requires the context-specific consideration of numerous unintended effects such as adverse selection or non-additionality. The increase in understanding of the complexity of land users' decision-making processes (Bartkowski and Bartke, 2018) adds to the challenge by demonstrating the inadequacy of existing instruments. However, effective and efficient policy mixes are essential to align the management of soils with the public preferences for soil-based ecosystem services.

Conclusions

Soils are scarce, both in terms of quantity and, especially, quality. They provide multiple benefits to humans, in the form of soil-based ecosystem services. However, this multifunctionality is characterized by trade-offs. Many of the ecosystem services provided by soils are collective goods, which implies that they will be underprovided in the absence of additional incentives. The extent of underprovision depends on the public preferences for soil-based ecosystem services, which can be estimated by means of economic nonmarket valuation. This can then inform the design of policy instruments required to align soil management with public preferences and to optimize soil management so as to enhance the multifunctionality.

To protect soils effectively and efficiently, it is necessary to understand the relevant economic effects adequately. For instance, soils are heterogeneous; therefore, their potential to provide ecosystem services, the opportunity costs of their protection as well as

the most effective management practices vary spatially. Economic valuation can help illuminate the extent of public preferences for non-private soil-based ecosystem services, but not all valuation methods are equally adequate and precise; any number may not be significantly better than no number at all. Furthermore, when designing policy instruments, challenges that arise from information asymmetry in the principal-agent setting need to be properly taken into account to avoid wasting scarce resources that could otherwise be used to finance the provision of other public goods.

Abstract

The links between soil and human health are many; they include essential nutrients, food security, exposure to pollutants and pathogens, beneficial organisms, medications, and clean water. Ancient civilizations were aware of the influence of soil on human health, but scientific study of the relations is more recent. Human health benefits from the biological, chemical, and physical properties and processes in soil. We embrace the following aspects of the relations: history, soil and food security, nutrition and four important trace elements, effects of soil entering the body, pollutant effects of metals, organic chemicals, radionuclides, and soil organisms, and medicines from soil.

Key points

- Some relations between soil and human health were known in ancient history
- Soil and food security are under increasing pressure because of growth in the world's population with potentially serious consequences for human health
- Trace elements from soil play a vital role in human health; we focus on iodine (I), iron (Fe), selenium (Se) and zinc (Zn)
- Soil can enter the human body by ingestion, inhalation or through skin lesions and can affect human health
- Some metal elements, organic chemicals, radionuclides and organisms can have a deleterious effect on human health
- Soil has been an important source of microorganisms that have provided medicines such as antibiotics.

Introduction

There is a multitude of links between soil and human health, including the supply of essential nutrients through the soil–plant–(animal)–food system, food security, exposure to pollutants and pathogens, the effects of beneficial organisms, production of medications, and purification of water. All the human health benefits supplied by soil take advantage of various aspects of the biological, chemical, and or physical properties of soil.

Recognition that soil influences human health goes back thousands of years, but the scientific study of the links between soil and human health is much more recent. There has also been a major increase in interest concerning the relations between soil and human health in recent years, with identifiable trends that aligned with major events. For example, a large amount of attention was focused on radionuclides deposited on the soil and entering the food chain after the testing of atomic bombs in the 1950s and 1960s and following accidents at the Chernobyl and Fukushima nuclear plants. Increased attention has also been given to organic

chemicals and 'heavy' metals as the environmental movement gained momentum in the 1970s and 1980s and this continues to the present (Brevik and Sauer, 2015).

The goal of this chapter is to provide a brief, relatively comprehensive overview of the connections between soil and human health, which will serve as a good primer for those who want an introduction to the topic. A number of recent review articles have discussed various aspects of the soil and human health relationship, providing broad overviews of the topic (e.g. Oliver and Gregory, 2015; Brevik et al., 2020), links to ecosystem services (e.g., Keith et al., 2016), and the influence of soil health on human health (Kemper and Lal, 2017). Reviews such as these, and the numerous references cited in them and in this chapter, can provide additional information as needed.

History of soil and human health

People have been aware for a long time that the environment affects their health either directly or indirectly through their food and drinking water, and the air they breathe. Several early civilizations referred to relations between the environment and human health; they drew their inferences from repeated observations of conditions rather than from scientific investigation. Scientific study of the role of the soil on animal and human health is little more than 100–200 years old, but the notion that soil has such a role goes back to at least 1400–1500 BCE (Brevik and Sauer, 2015). Around 1550 BCE an Egyptian physician collected medical facts about many health issues that he recorded on papyrus (now known as the Ebers Papyrus, 1500 BCE), which was later sealed in a tomb near Thebes and obtained by Georg Ebers in 1872. The Bible also depicts Moses as understanding that fertile soil was essential to the well-being of his people in about 1400 BCE as he entered Canaan after leaving Egypt (Numbers 12, 18–20) (Brevik and Burgess, 2013). Despite such early observations, most of these effects remained unexplained until the twentieth century, and some still remain so.

Archeologists and medical historians have identified evidence of poor health from tissues and mummies from prehistoric times that can be linked to environmental conditions (see Davies et al., in Selinus et al., 2013). For example, goiter was prevalent in ancient China, Greece, Egypt and later the Inca state of Peru. It was often treated with seaweed, although people at the time did not know why the treatment was effective. The practice was based on observations and on trial and error. Archeologists have also noted relations between health and the environment from the analysis of bone, teeth, diet and the nutritional status of prehistoric humans and animals (Szostek and Glab, 2001). For example, the change from a hunter–gatherer society to an agricultural-based economy led to major dietary change and to evidence of iron (Fe) deficiency, i.e. iron deficiency anemia (Roberts and Manchester, 2007). This is because iron in plants is more difficult to absorb than that from meat.

The ancient Greeks can be regarded as more or less founding the basic concepts of modern medicine which they based on ideas from Egypt. The work of Hippocrates (a Greek physician, ca 460 BCE–377 BCE) and his fellow workers resulted in the recording of many scientific facts, probably beginning the tradition of studying the causes of diseases rather than simply observing the symptoms when prescribing a cure. Hippocrates noted in his treatise *Airs, Waters, Places* (see Brevik and Sauer, 2015) that water comes from soil, which further links with the list provided for consideration in a proper medical evaluation that included the ground: "... whether it be naked and deficient in water, or wooded and well-watered, and whether it lies in a hollow, confined situation, or is elevated and cold...". In this book he also mentions the soil in relation to the environment six times.

Hippocrates and his co-workers recognized that some diseases were always present in a given population, i.e. 'endemic,' whereas others that were not always present but which occurred in greater frequency at certain times, they called 'epidemic.' The introductory paragraphs of Hippocrates's *Airs, Waters, Places* summarize key factors such as climate, quality of the soil, water, way of life and nutrition (Rosen and Rosen, 1993). For more than 2000 years, this was the basic epidemiological text that provided the theoretical underpinning for understanding endemic and epidemic diseases. No fundamental change occurred until the late nineteenth century when new sciences, such as bacteriology and immunology, emerged (Tountas, 2009). Ideas from the era of Hippocrates about the environmental determinants of health are still relevant.

From the seventeenth to the nineteenth centuries there was increasing awareness of the links between the soil and human health, but until the middle of the twentieth century much of this was anecdotal (references to many points in this paragraph are given in Brevik and Sauer, 2015). Nevertheless, in 1876 Robert Koch determined that anthrax was caused by the soil-borne pathogen *Bacillus anthracis*. There were several other developments toward the end of the nineteenth century to support the effects of soil on human health such as *Mycobacterium leprae* (leprosy; 1873), *Clostridium tetani* (tetanus; 1884) and *Escherichia coli* (1885), for example. In the early 1920s experiments were designed to investigate relationships between soil and health. *Medical Testament*, published in the United Kingdom in 1939, indicated that illness in the UK was increasing because of poor nutrition related to agricultural practices that depleted nutrients in the soil. At the same time (1938) the United States Department of Agriculture (USDA) *Yearbook of Agriculture* stated the importance of minerals from the soil in food on the well-being of animals and humans. The isolation of antibiotics from soil bacteria by Selman Waksman in the 1940s was a major breakthrough (see below). In 1946 Eve Balfour, who studied agriculture at Reading University College during WWI, established the Soil Association arising from her understanding of the relations between soil and health. In 1959 André Voisin's book showed how this topic was gaining momentum and that the medical profession should give more attention to deficiencies in the soil. Toward the end of the twentieth century research was increasing to provide greater understanding of the role of soil in several types of human illness. Nevertheless, major gaps in knowledge remain and the need for focused research continues.

The early 21st century has seen a growth in interdisciplinary research which is fundamental for progress in our knowledge of the relations between soil and human health. However, direct knowledge of these relations remains difficult to obtain by empirical means. With the development in genomic methods greater understanding of some aspects of the relations are possible. With safer and more nutritious food we should need less medical care and have a better quality of life.

Soil and food security

The concept of food security developed over several decades from the 1970s, leading to the most commonly used current definition: the state when “all people, at all times, have physical and economic access to sufficient, safe, and nutritious food to meet their dietary needs and food preferences for an active and healthy life” (FAO, 1996). Food security is complex because it involves many factors and systems. The availability of food depends on suitable land and soil for agriculture, natural conditions, and socio-economic conditions, all of which have multiple facets (Fig. 1).

To achieve food security for all people is a huge challenge with an increasing population (1950 2.5 billion; 2021 7.9 billion), changes in eating habits, social balances and land ownership, climate change and increasing degradation of the soil. Over the past 50 years food production has largely kept pace with demand, but there remain approximately 2 billion people worldwide in moderate to severe food insecurity. This has two facets, the lack of sufficient food and of certain essential elements. The former is widespread in the developing countries of Africa, Asia and parts of Latin America, but the latter can affect both developed and developing countries. In addition, the COVID-19 pandemic of 2020–2022 has increased food insecurity dramatically in almost every country.

Insufficient food leads directly to ‘protein–energy’ malnutrition caused by a lack of carbohydrates, proteins and fats in the diet; there is also a deficit in all major macronutrients and certain micronutrients. Some causes of food security are linked to under-nutrition and are related to the soil or agriculture, whereas others are social and political (Table 1). Under-nutrition leads to stunted growth, poor health, disability, wasting of muscle and fat reserves, and an increased risk of diabetes and cardiovascular disease in adulthood. It impairs the immune system and enhances the effects of toxic elements on humans. Food security is also related to poverty because people cannot afford to buy food even if it is available. There are strong social forces at play in such situations.

The soil affects food availability and its quality: it is the basis for 98.8% of the food consumed by humans. The concept of food security is well established, but that of soil security is in its infancy. Soil is the means to provide food, fiber and biofuels, but this must be done sustainably. Soil is a fragile and essentially non-renewable resource that has suffered degradation in many parts of the world. Increasing demands on the soil and degradation have sometimes led to an unstable system in which the soil becomes more vulnerable to threats and less able to perform its functions.

Inherent soil fertility embraces nutrient availability, stable porous structure, large available water content and diverse microbial and faunal communities that facilitate root and shoot growth. These can be maintained or improved by sustainable management practices, including modern technologies. The use of crop rotations, cover crops, crop residues, animal and green manures and other organic wastes can improve soil fertility, soil organic matter (SOM) content and mitigate soil degradation. Organic farming alone cannot resolve issues of food security because of its generally smaller yields, therefore, integrated management should be considered that includes the use of organic and mineral fertilizers to maintain both human and soil health.

Fig. 1 The factors and systems that link to form the complex web of food security.

Table 1 Essential mineral nutrients (in addition to carbon, hydrogen and oxygen) in plants and mammals, together with their recommended daily allowance (RDA) or adequate intake (AI – where no RDA has been established) in humans, function in mammals and common sources in the human diet.

Element	Essentiality		RDA or AI/mg	Function in mammals	Common sources in the human diet
	Plants	Mammals			
Primary element					
Calcium (Ca)	Yes	Yes	1300	Essential constituent of bones and required for synthesis and function of blood cells, and function of muscle, heart and digestive system	Kale, collards, mustard greens, broccoli, dairy products
Nitrogen	Yes	Yes	105	Essential constituent of DNA, RNA and proteins	Beans, lentils, beef, lamb, cheese, eggs, milk
Phosphorus (P)	Yes	Yes	700	Essential constituent of bones, cells and energy processes plus other functions	Nuts, beans, peas, lentils, grains, meats, eggs, dairy products
Potassium (K)	Yes	Yes	4700	A systemic electrolyte and essential in regulating ATP with sodium	Fruits, cereals, vegetables, beans, peas, lentils, dairy products, meats
Secondary element					
Magnesium (Mg)	Yes	Yes	420	Required for bones and processing ATP	Seeds, nuts, beans, peas, lentils, whole grains, dark green vegetables
Sulfur (S)	Yes	Yes		Constituent of amino acids – diets with sufficient protein contain adequate sulfur so there is no RDA	Bok choy, broccoli, brussels sprouts, cabbage, cauliflower, collard greens, onions, shallots, leeks, garlic
Chlorine (Cl)	Yes	Yes	2300	Pump functions of cells and hydrochloric acid in stomach	Dairy products, meats, eggs
Trace element					
Boron (B)	Yes	Yes		Has a role in some animals in vitamin D activation, but uncertain whether this is a nutritional effect. Helps to build and maintain bones and is involved in Ca and Mg metabolism	Raisins, peanuts, fruits, beans, broccoli, carrots, onions, dark green leafy vegetables
Iron (Fe)	Yes	Yes	18	Required for many proteins and enzymes particularly hemoglobin in blood	Meats, especially red meat
Manganese (Mn)	Yes	Yes	2.3	A cofactor in enzyme reactions	Whole grains, beans, peas, lentils, nuts, tea
Copper (Cu)	Yes	Yes	0.9	Required component of many redox enzymes	Beans, peas, lentils, whole grains, nuts, peanuts, mushrooms, chocolate, organ meats (offal)
Zinc (Zn)	Yes	Yes	11	Required component of many enzymes	Nuts, whole grains, beans, peas, lentils, meats, organ meats (offal)
Nickel (Ni)	Yes	Yes		Suggested role in some animals in enzyme function and iron adsorption and metabolism in humans	Dry beans, cocoa products, some nuts, wheat, shellfish, vegetables
Molybdenum (Mo)	Yes	Yes	0.045	Component of several oxidase enzymes	Beans, peas, lentils, dark green leafy vegetables, organ meats (offal)
Sodium (Na)	Beneficial	Yes	1500	A systemic electrolyte and essential in regulating ATP with potassium	Dairy products, meats, eggs
Selenium (Se)	Beneficial	Yes	0.055	An essential cofactor of antioxidant enzymes	Grain products, nuts, especially Brazil nuts, garlic, broccoli (if grown on high-Se soils), meats from Se-fed livestock, seafood
Cobalt (Co)	Beneficial	Yes		Required in the synthesis of vitamin B ₁₂ (cobalamine) which is synthesized by bacteria	Green vegetables, cereals, mushrooms
Minimum trace element					
Aluminium (Al)	Beneficial			No known function in healthy humans but known toxic effects	
Silicon (Si)	Beneficial	Possibly		Possible beneficial role in human bone health and wound healing	Cereals, pumpkins, water
Human trace element only					
Iodine (I)		Yes	0.15	Essential for the synthesis of thyroid hormones, possibly as an antioxidant and for the functioning of mammary and salivary glands	Vegetables, cereals, fruit
Fluorine (F)				Not an essential nutritional element but can help in the prevention of dental cavities	Tea, kale, leeks, lettuce, mustard, onions, peas, spinach, tomatoes, organ meats (offal), fish
Human minimum trace element					
Lithium (Li)		Possibly		Physiological function unknown but feeding studies have suggested benefits in some animals	Vegetables, drinking water
Vanadium (Va)		Possibly		Not essential, but is a cofactor that enhances or inhibits some enzymes	Parsley, leafy vegetables, asparagus, rye, black pepper, mushrooms
Chromium (Cr)		Possibly		Not essential although some studies suggest a role in sugar metabolism	Pulses, nuts, meats, seafood
Toxic trace					
Arsenic (As)		Possibly		May play a role in DNA methylation and cancer prevention, but also toxic effects	Rice, seafood
Cadmium				No known function in healthy humans, but known toxic effects	
Lead (Pb)				No known function in healthy humans, but known toxic effects	

Adapted from Table 1, Oliver MA and Gregory PJ (2015) Soil, food security and human health: A review. *European Journal of Soil Science* 66: 257–276.

During the last 50 years the global population has tripled and production of the major cereal grains (maize (*Zea mays* L.), wheat (*Triticum aestivum* L.), rice (*Oryza sativa* L.) and barley (*Hordeum vulgare* L.)) has also tripled, furthermore diets have changed to consume more meat. Fairly recent technological innovations and intensified production have had some adverse effects on the environment. For example, excessive applications of nitrogen and phosphorus have polluted fresh and coastal waters, and intensive land use and vegetation clearance have resulted in soil and land degradation. Soil organic matter has also declined, and this maintains many key soil functions that underpin fertility and resistance to erosion. This is also associated with a loss of soil biodiversity which can affect the soil's ability to perform many ecosystem functions. Some elements occur in potentially toxic concentrations that diminish crop yields and can accumulate in the food chain with detrimental consequences for human health. Salinization and desertification reduce the availability and productivity of land for food production. Compaction from the large machinery used in intensive agriculture leads to reduced yields and increased erosion. Nutrient mining leads to decreased productivity and food security. This is a major problem in the tropics. In most of Sub-Saharan Africa and Asia the soil supports only poor yields because it is either inherently infertile, over used or it requires the addition of fertilizers. Degradation further impoverishes farmers in developing nations because they lack the resources to remedy the situation, leading to greater food insecurity, under-nutrition and poor health.

The nutritional value of many foods is markedly affected by the soil, especially where food is produced and consumed locally. In complex food chains where food derives from different sources and processed foods are often supplemented with essential minerals and vitamins the effects of soil are less evident. Crops require 14 mineral elements (listed in Table 2) and deficiency in any one reduces crop yields. In addition to these elements, humans require small amounts of several other trace elements, most of which are from plants. Deficiencies in trace elements occur worldwide (see below). The diets of more than two-thirds of the world's population lack or are deficient in one or more of these essential mineral elements, with more than 60% deficient in Fe, >30% in Zn, almost 30% in I and about 15% in Se. Deficiencies of calcium (Ca), copper (Cu) and magnesium (Mg) are also prevalent in many countries.

Nutrient malnutrition also results from crops produced on soil with poor phytoavailability of the elements essential to human nutrition. Although plant breeding has increased the calories and protein in human diets, the nutritional health of many people, in both developing and developed countries, has deteriorated. Nutrient deficiencies can have far-reaching consequences to human health, but they are often disregarded because they can be difficult to identify. They can result in anemia, diseases of the immune system, mental retardation, and cardiovascular diseases, to name but a few, and have more impact during pregnancy, lactation and periods of rapid growth (childhood). Table 3 summarizes health disorders linked to a range of trace element deficiencies. Nutrient deficiencies are most likely to be evident in developing countries. Nevertheless, they might be an underlying factor for many diseases in developed countries, particularly selenium and zinc.

Future food security will depend on a major change in attitude in agriculture toward sustainable intensification that will halt further degradation of the soil. There is an urgent need to regenerate the soil by matching inputs to the needs of the crop and soil, increase soil organic matter content, remediate contaminated land, improve the quality of irrigation water and scheduling, and the use of technology and precision agriculture.

Nutrition and selected trace elements

Crops require 17 mineral elements, 14 of which are obtained from soil (Table 1). Deficiency in any one restricts plant growth and reduces crop yields. In addition to these elements essential for plants, humans require small amounts of an additional 13 trace elements (Table 1). Humans get most of these elements from plants (Brevik et al., 2020); hydrogen (H), (oxygen) O₂, carbon (C), nitrogen (N), sodium (Na), potassium (K), Ca, Mg, phosphorus (P), S and chlorine (Cl) make up about 99.9% of atoms in the human body and all, except for H, O₂ and C, have soil as their source (Table 1). The remaining 0.1% of atoms come from trace elements. Trace elements can have both beneficial and toxic effects on humans, especially where the range for optimal intake is narrow. The trace elements required by humans cannot be synthesized; therefore, there is a direct link between soil, food and under-nutrition (McMillan, 2002). The diets of more than two-thirds of the world's population lack or are deficient in one or more of these essential mineral elements (White and Broadley, 2009).

Mineral deficiencies occur worldwide, but some elements also occur in potentially toxic concentrations that diminish crop yields. Such elements may be taken up by plants and animals and accumulate in the food chain with detrimental consequences for human health (Oliver and Gregory, 2015). We focus on four trace elements only (iodine, iron, selenium and zinc) because of space, but the deficiencies of these are known to have substantial effects on human health.

Iron

Soil affects the amount of iron in food, but its absorption by humans is complex and depends on many factors (Table 1). Availability of Fe to plants is limited by its solubility in soil which decreases from the amorphous iron oxides to ferrihydrate to goethite to hematite. In aerobic soil, the activity and availability of Fe³⁺ is enhanced by many soil bacteria and fungi.

Iron deficiency in soil, plants and animals results in too little Fe in the human diet. Iron-deficiency anemia (IDA) is one of the most severe effects of nutritional deficiencies in the world affecting some 25% of the world's population and about 47% of

Table 2 A summary of soil and other associated factors that affect human health.

	<i>Human health</i>	<i>Soil factors</i>	<i>Other factors</i>	<i>Food sources of elements</i>
Food insecurity Under-nutrition	Protein–energy malnutrition, stunted growth, disability, immunocompromised, death.	Poor soil, poor nutrient status and maintenance, organic matter and biodiversity depletion, salinization, sodification, acidification, drought, desertification, compaction, wind and water erosion	Transport and distribution, poverty, politics, economics, loss of agricultural land to other uses	
Food quality – elements				
Hidden hunger				
Iron (Fe)	Present in hemoglobin, myoglobin. Iron deficiency anemia (IDA) – cognitive development in children, pregnancy, reduced immunity and thyroid function.	Poor bioavailability – Fe^{2+} more available than Fe^{3+} . Deficiency occurs in aerobic, sandy, calcareous and alkaline soil types. Toxicity occurs in anaerobic and acid ($\text{pH} < 5.5$) soil. Availability depends on redox potential, pH and microbiology (siderophores and phytosiderophores).	Deficiency in food affects humans. Deficiency and toxicity reduce crop yields. Fertilizers can maintain Fe status but expensive. Zinc enhances Fe absorption by humans.	Red meats, liver, egg yolk, dried fruits, beans, lentils.
Iodine (I)	Hypothyroidism - goiter, irreversible brain damage, cretinism, mental retardation and perinatal mortality.	Dry and wet deposition from atmosphere, volatilization from soil and re-deposition. Soil organic matter, microbial activity, texture, Eh and pH affect I fixation. Bioavailability depends on redox and $\text{pH} - \text{IO}_3^-$ (iodate) more available than I (iodide).	Deficiency in humans – deficiency in food and presence of goitrogens. Selenium involved with I in synthesis of thyroxine.	Cod, shellfish, eggs, seaweed, milk, cranberries.
Selenium (Se)	Deficiency – reduces antioxidant and redox functions. Linked to coronary diseases, miscarriage, malignancies. Toxicity – selenosis.	Deficiency is more widespread than toxicity. Microbial processes, pH and redox potential affect Se status. Selenate generally more available than selenite, although some challenge this.	Fertilizers effective in supplementing Se (see example from Finland).	Brazil nuts, cashew nuts, shellfish, tuna, swordfish, seeds, whole grains, meats.
Zinc (Zn)	Metabolic promoter. Gene expression. Deficiency affects physical growth, immune system, reproductive health, dermatological conditions, neurobehavioral problems.	Deficient on leached tropical, sandy, calcareous, alkaline and flooded soil types. Toxic in soil with $\text{pH} < 4$ and deficiency common in soil with $\text{pH} > 7$ and large concentrations of phosphate. Redox status affects form.	Cu inhibits Zn uptake in plants.	Meats, shellfish, whole grain cereals, sesame and pumpkin seeds, pulses, cashew nuts.
Environmental factors				
Elemental contamination	Arsenic (As) (vascular disorders), cadmium (Cd) (kidney and liver disease), fluorine (F) (fluorosis), lead (Pb) (neurological damage and hematologic effects), Zn (reproductive effects).	Toxicity by metals may relate to geology, mining, industrial activity, fertilizers, pesticides, windborne dusts, sewage sludges, irrigation. May accumulate in plants and be ingested or may be ingested directly from soil by mouth or inhalation.	Soil degradation can lead to increased wind and water transport over long distances of soil pollutants.	
Organic chemical contamination	Carcinogenic, neurological and immune problems.	PCBs, PAHs, carbamates, furans accumulate in soil from industry, pesticides and applied biosolids. Some persist in soil (POPs) and enter food chain.	Sources food, windborne dust and soil. Children are most susceptible.	
Pharmaceutical contamination	Emasculation resulting from estrogen in environment. Antibiotic resistance from environmental effects. Unknown human effects from additive effects of mixtures of compounds.	Sewage water and sludges applied to land contain a range of pharmaceutical agents.	Antibiotics and other drugs given to animals enter the environment from sewage sludges with largely unknown effects.	
Soil pathogens	Bacteria (anthrax, tetanus), fungi (Valley fever), protozoa (diarrhea) helminths (anemia, ascariasis), prions (transmissible spongiform encephalopathies).	Occur naturally in soil, some related to anthropogenic activity. Transported long distances by wind. Ingestion by mouth, skin lesions and inhalation.	Desertification and salinization: poor crop cover resulting in greater soil transport of dust containing pathogens.

Table 3 Examples of health problems that can be caused by nutrient deficiencies.

Nutrient	Deficiency diseases/problems
Boron	Osteoporosis, inflammation, atherosclerosis, prostate cancer, neurological problems
Calcium	Low bone mass, osteoporosis, arteriosclerosis, hypertension, degenerative joint diseases
Chromium	Glucose intolerance, diabetes, hyperlipidemia, peripheral neuropathy, encephalopathy, cardiovascular disease
Copper	Hypochromic microcytic anemia, neutropenia, Alzheimer's, ischemic heart disease, hypercholesterolemia, osteoporosis, reduced immunity, cardiovascular disease, secondary iron deficiency
Fluorine	Dental caries, osteoporosis
Iron	Iron-deficiency anemia, fatigue, cognitive impairment, reduced immunity, preterm delivery, fetal growth retardation
Iodine	Goiter, hypothyroidism, mental retardation, cretinism, perinatal mortality, congenital anomalies, cancer
Magnesium	Cardiovascular disease, arteriosclerosis, diabetes, obesity, metabolic syndrome, hypertension, osteoporosis, diabetes, cancer, asthma, muscle weakness
Manganese	Weight loss, transient dermatitis, nausea
Molybdenum	Stomach and esophagus cancer, tooth decay
Nickel	Glucose intolerance, osteoporosis
Phosphorus	Anemia, reduced immunity, muscle weakness, osteoporosis
Potassium	Hypertension, cardiovascular disease, muscle weakness, dementia, abnormal heartbeat, diabetes, stroke
Selenium	Keshan and Kashin–Beck diseases, inflammation, reduced immunity, pseudo albinism, cancer, phenylketonuria, mental retardation
Sulfur	Pain, allergic rhinitis
Vanadium	Hypertension, glucose intolerance
Zinc	Stunted growth and learning, psychomotor and neurobehavioral problems, adverse impacts on maturation of spermatozoa and fetal development, weakened immune system, acrodermatitis enteropathica, pustular dermatitis, alopecia, diarrhea, emotional disorders, weight loss, infections, immune dysfunctions, hypogonadism in males, neurosensory disorders, problems with the healing of ulcers

pre-school children (WHO, 2008 see website reference). Iron-deficiency anemia impairs the cognitive development of children from infancy to adolescence and immunity leading to increased susceptibility to infectious diseases and mortality.

Iodine

Iodine was the first element to be recognized as essential to human health. Goiter is the most obvious effect of iodine deficiency, but the more insidious effects are mental retardation, cretinism and perinatal mortality. Cretinism may affect 5–15% of the population in areas of endemic I deficiency.

The main source of iodine in soil is from the oceans by atmospheric deposition in either rain or dry deposits (Table 2). There is no simple correlation between I in soil and distance from the sea, although the largest concentrations are typically 0–50 km from the shore. Iodine deficiency occurs worldwide; it is most pronounced in high mountain areas, inland areas of continents and some alluvial plains. The soil's potential to fix iodine affects its concentration, which depends principally on soil organic matter content, but also on other soil properties given in Table 2. The bioavailable fraction (Table 2) important for health is iodide, which is favored by acidic and anaerobic conditions. In general <25% of soil iodine is immediately available (see Fuge, 2013). The less mobile and available iodate occurs in dry, oxidizing, alkaline conditions such as in calcareous soil. Fig. 2 summarizes the main features of the iodine cycle. Biological methylation of iodine (CH_3I) in soil by a variety of bacteria plays an important role in its transfer to the biosphere.

Insufficient I in crops, animal products and drinking water are the primary causes of iodine deficiency diseases. The effects of iodine deficiency on human health are among the most serious of the trace element deficiencies especially for pregnant women and young children. Iodine is required in only minute amounts, but it is essential in the thyroid gland to synthesize thyroxine, which is crucial for growth and development.

Selenium

Selenium occurs in soil as selenide (H_2Se), selenate (SeO_4^{2-}), selenite (SeO_3^{2-}), elemental Se and organic forms such as selenomethionine and selenocysteine. Selenite is more strongly adsorbed by soil and is less soluble and more stable than selenate. Acid conditions favor the stability of selenite (Se^{4+}).

Selenium is an essential trace element for humans with a narrow range between dietary deficiency (<40 μg Se per day) and toxicity (>400 μg Se per day). Severe human deficiency in Se is rare; the main examples are in China where Keshan and Kashin–Beck diseases are evident (Oliver and Gregory, 2015). Many people, however, have too little Se in their diet with possibly 0.5–1 billion people directly affected by Se deficiency.

Selenium deficiency is implicated in a wide range of medical conditions (Tables 1 and 3). It reduces the antioxidant and redox functions of selenoproteins making people more prone to viral infections (Fairweather-Tait et al., 2011), inflammation and environmental pollutants. Selenium has been added to fertilizers since 1984 in Finland by law.

Fig. 2 Schematic diagram that summarizes the main features of the iodine cycle. Adapted from Fig. 5, Oliver MA and Gregory PJ (2015) Soil, food security and human health: a review. *European Journal of Soil Science* 66: 257–276.

Selenium toxicity in humans, which can cause selenosis, is much less common than deficiency. Toxic concentrations, $>3 \text{ mg Se kg}^{-1}$, can occur locally on seleniferous parent materials and can also result from irrigation with Se-rich water.

Zinc

Zinc deficiency affects about a third of the world's population. In children it causes stunted growth and learning, psychomotor and neurobehavioral problems. It also affects the formation and maturation of spermatozoa and fetal development and the immune system. Severe Zn deficiency gives rise to acrodermatitis enteropathica (a genetic disorder), pustular dermatitis, alopecia, diarrhea, emotional disorders, weight loss, infections, immune dysfunction hypogonadism in males, neurosensory disorders and problems with the healing of ulcers.

The solubility of Zn is generally small and pH dependent (Table 2). Factors affecting Zn availability to plants are total Zn content, pH, contents of organic matter, clay and calcium carbonate, redox conditions, microbial activity in the rhizosphere, soil moisture status, concentrations of other trace elements and macronutrients, especially P, and climate (Alloway, 2008). Copper and large phosphate concentrations in soil can cause Zn deficiency. Although Zn is not susceptible to oxidation or reduction, the soil's redox status can affect its form in soil.

Zinc is essential for animal and human health although the effects of its deficiency in humans were not recognized until the 1960s. Zinc deficiency can be overcome by its addition to fertilizers, which increase Zn bioavailability in the diet.

Effects of soil entering the human body

Humans can be exposed to soil directly by the pathways of ingestion, inhalation during respiration and absorption or penetration of the skin, i.e., dermal contact. These pathways result in exposure to: (i) toxic chemicals that can be carcinogenic, can adversely affect cognitive and respiratory function, growth and fertility; (ii) pathogens such as bacteria, fungi and helminths; and (iii) small irritant particles such as asbestos and clays.

Ingestion

Soil can be ingested involuntarily by eating contaminated food such as unwashed vegetables and fruits and by hand-to-mouth activity, which is especially prevalent in children. If the soil is contaminated with metals, organic chemicals, or pathogens this can result in adverse health effects. The nervous systems of small children are especially sensitive to Pb, more of which can accumulate in their brains than in older people because of the incomplete development of the blood–brain barrier. Lead is a cumulative element in the body and according to the World Health Organization (WHO, 2019 – see website below), “there is no level of exposure to lead that is known to be without harmful effects.”

The deliberate consumption of soil, especially clayey soil, has a long history and is amazingly widespread. The term geophagy was coined in ~1850 to describe this custom, however, it has existed for at least two millennia. Clark (1969) described an anomalous clay layer at a prehistoric site at the Kalambo Falls in Zambia indicating that clay might have been eaten by hominids

(*Homo erectus* or *Homo sapiens*) (see “History of soil and human health”). Von Humboldt reported that clay was eaten by the Otomac tribe along the Orinoco River, and he saw mothers give their children lumps of clay in Peru to keep them quiet. Geophagia is most common in developing countries where there is poverty and many people suffer from malnutrition. Clay is traded for consumption in India, Africa and the USA, among other locations. Recent research suggests that there are two main explanations: (i) to compensate for mineral deficiencies and detoxification, or (ii) that it is learned behavior, i.e. cultural. Clay soil can release essential elements that humans require by cation exchange, such as Cu, Fe, Mg, Mn (manganese), K (potassium), Si (silicon) and Na, in the acid conditions of the stomach. Geophagy is not necessarily beneficial because, for example, Ca-rich clay can affect the utilization of Zn and Fe, and inhibit their absorption by the body. Avicenna (980 to 1037 CE) suggested that geophagia led to anemia. It can also result in the ingestion of harmful bacteria, parasites and environmental pollutants.

Johns and Duquette (1991) suggested that detoxification is a more satisfactory explanation for geophagy because clay soil can absorb dietary toxins, such as alkaloids, tannin, and bacterial toxins. They indicated that clay was used to make acorns more palatable and to detoxify bitter potatoes (*Solanum* spp.). The clays used for geophagy have a large cation exchange capacity and specific surface area; they can absorb and adsorb elements and microbes. Kaolin and smectite clays are effective in medicinal use because they can bind with toxins, aflatoxins and bacteria. Because of their effect on the intestinal mucosa, clays can reduce nausea, diarrhea, and intestinal pH.

Soil is often contaminated with enteric bacteria and helminths when it is ingested. For example, *Campylobacter*, *Escherichia coli* and *Shigella* spp. are Gram-negative bacteria that do not form spores, and possibly cause up to 6 million deaths per year. They are the second most common cause of infant mortality. Most helminths are nematodes; they include hookworm, round worms, whipworms and pinworms. There are probably two billion people worldwide infected by helminths, and Bultman et al. (see Selinus et al., 2013) suggested that 130,000 deaths per annum are caused by nematode infections. The history of human health (see above) shows that they have always been part of human existence. *Ascaris lumbricoides* (round worm), which causes ascariasis, an infection of the small intestine, is the largest and most widespread nematode. Infections result from poor sanitation and infected soil ingested directly or from dirty vegetables and fruit. Helminths are transmitted by eggs present in human feces, which contaminate soil in areas where sanitation is poor. Adult worms live in the intestine where they produce thousands of eggs each day. In areas that lack adequate sanitation, these eggs contaminate the soil. They produce a wide range of symptoms including diarrhea, abdominal pain, general malaise and weakness.

Inhalation

Soil can be inhaled as dust, especially in dry regions with fine soil. There has been increasing recent realization that dust inhaled from urban soils can contain metals and other contaminants from industrial and domestic emissions, buildings, fuels, roads and tyre particles. Cadmium and lead are of particular concern for human health because of their accumulation in the body. Contaminated soil can be transported over very long distances.

Soil rich in fibrous minerals such as tremolite and erionite (asbestos-like minerals) are known to cause malignant pleural mesothelioma. There are examples of such effects in Cappadocia, central Turkey and northeast Corsica, together with concerns in western North Dakota, USA.

Pathogens can be inhaled easily because of their small size. The fungal pathogen *Coccidioides immitis* causes Valley Fever (coccidioidomycosis) in the southwestern USA. The yeast-like fungi *Cryptococcus neoformans* and *C. gattii* occur in the soil of tropical and sub-tropical regions. Inhalation of their spores leads to cryptococcosis in humans, which can affect the nervous system as cryptococcal meningitis or the lungs as pneumonia (Redshaw et al., 2013). Over the past decade or so outbreaks of disease associated with *C. gattii* have occurred in temperate regions of Canada and the USA; these might be a response to a warming climate. Infection from *Hantavirus* can result from inhalation of wind-blown particles from infected soil. This can occur with tillage of soil when loose material containing *Hantavirus* might be inhaled. Infections can cause either ‘hantavirus pulmonary syndrome’ (HPS) or ‘hemorrhagic fever with renal syndrome’ (HFRS). Hantavirus infections can occur worldwide, but in the USA most cases occur in the arid and semiarid western states. Pathogens in raw sewage used for irrigation in dry areas can be easily picked up and transported by the wind and then inhaled. This could also be an important pathway for arsenic and lead to enter the body.

Radon is a radioactive gas that humans inhale in certain areas and which causes malignancies. Radon decays to solid daughters, e.g. ^{218}Po (polonium), ^{214}Pb , ^{214}Bi (bismuth) and ^{214}Po , and epidemiologists suspect that inhaled radon and the solid decay products retained in the lungs lead to or contribute to lung cancer. However, it is also implicated in other forms of cancer, including certain childhood ones. Radon accounts for about 50% of the radiation dose received by people living in the United Kingdom.

Soil absorption through skin lesions

One of the most common diseases associated with soil is tetanus which results from infection by *Clostridium tetani* when it enters the body through cuts and abrasions. These anaerobic bacilli occur in the intestines of man and other animals and enter the soil from feces. Spores from the bacterium can remain dormant in the soil for many years and then germinate and multiply in the anaerobic conditions of human tissue. The bacilli remain localized but they produce an exotoxin that passes into the blood stream which affects the motor nerve endings and cells. It causes spasm and convulsions, and death in about 50% of cases. The disease is well controlled by immunization.

Parasites such as hookworm can also enter the body through abrasions. Hookworm infects over 500 million of the world's population. There are two main species of hookworm, *Ancylostoma duodenale* and *Necator americanus*. Their eggs hatch to rhabditi-form larvae and then become filariform larvae. The latter enter the body through abrasions in the feet and pores in skin, then move through the blood stream into the lungs, trachea and esophagus. When adult they attach themselves to the walls of the small intestine where they produce their eggs which are then defaecated to complete the cycle. They cause bleeding which causes anemia when the infestations are severe.

An interesting link between soil and human health is a non-filarial elephantiasis called Podoconiosis, a form of lymphoedema that causes swelling of the lower legs resulting from blockage of lymph nodes by soil. It appears to be associated with being bare foot and with a particular type of fine clay soil that occurs in the tropics. Podoconiosis is now the most common form of elephantiasis. It has been suggested that micrometric particles of soil containing kaolinite, amorphous silica, some quartz and iron oxides penetrate bare skin and are engulfed by macrophages in the lymphatic system of the lower limb, inducing an inflammatory response in the lymphatic vessels leading to lymphoedema and fibrosis.

Soil organisms

There are several ways that soil organisms can be sub-divided. One is into micro- and macro-organisms based on size. Both micro- and macro-organisms play important roles in the overall soil ecosystem, and thus are critical for creating a suitable environment for crop production as well as several other ecological functions. However, the influence of soil microorganisms on human health has been extensively studied while similar work regarding macroorganisms is much rarer (Brevik et al., 2020). Another subdivision is based on the time the organism spends in the soil (Table 4), and from a soil and human health perspective is useful in understanding possible modes of transmission and infection. Classifying soil organisms as pathogenic or non-pathogenic, and what they are pathogenic to, is also important in soil and human health studies. Plant and human pathogens both impact human health; the plant pathogens do so indirectly with their influence on crop production and the human pathogens do so directly. Examples of a few common human pathogens found in soil are given in Table 5 and displayed in Fig. 3.

Human pathogens are often introduced to soil through anthropogenic activities. Disposing of sewage with on-site infrastructure such as septic systems, applying raw sewage effluent or manure (particularly human effluent or manure) to crops, and land disposal of municipal and clinical wastes are all ways that pathogens may be introduced to soil. Application of organic wastes to soil is an important part of a circular economy, and these wastes contribute to soil biological, chemical, and physical properties. Pathogens can be killed through proper composting prior to application of solid wastes to soil and treatments such as chlorine, ozone, or ultraviolet light prior to applying liquid wastes. A healthy soil ecosystem with much biodiversity can also help to keep pathogens under control (Wall et al., 2015).

Exposure to soil microorganisms likely plays an important role in developing and regulating the human immune system. Much of the study in this area has focused on allergic responses, with studies showing that those who were raised in environments where they were exposed to soil were considerably less apt to develop allergies than those raised where they had little soil exposure (Brevik et al., 2020). Soil microorganisms also seem to have positive influences on physical health. In mouse studies gut microbes acquired from soil increased anti-inflammatory response, and in humans providing a killed *Mycobacterium vaccae*, which is a common soil saprophyte, improved the performance of chemotherapy. Findings such as these indicate that having contact with soil microorganisms is beneficial to humans. Blum et al. (2019) have proposed that a close link has formed between the soil microbiome and the human intestinal microbiome during human evolution, and that this link continues to evolve as human lifestyles and settings change. They are particularly concerned that as humans have moved to a more urban lifestyle, with less soil contact, the human intestinal microbiome has been depleted, which has a negative impact on human health.

The soil ecological system, including both micro- and macro-organisms, is important in crop production. This occurs because organisms like earthworms and plant roots take part in creating soil voids and structure, which is critical to achieve satisfactory water infiltration and storage and aeration in the soil. Soil organisms also control the decomposition of soil organic matter, releasing plant available nutrients into the soil solution and creating glues that help bind primary soil particles into structural units. And soil organisms themselves add to soil organic matter, lending their tissues to the system when they die, which recycles the nutrients found in them. These relationships have been well-known for many years, and they are all important to the production of adequate

Table 4 Classification of soil organisms based on the amount of time they spend in the soil.

Classification	Time
Permanent	The organism is a permanent inhabitant of the soil and can complete its entire life cycle in the soil
Periodic	The organism requires part of its life cycle to be completed in the soil
Transient	The organism may be found in the soil naturally, but the soil is not required to complete its life cycle
Incidental	Organisms that are introduced into the soil through anthropogenic activities

Table modified from Collier D and Brevik EC (2021) Soils and human health: Communication between soil scientists and health care providers. In Lal R (ed.), *The Soil-Human Health-Nexus*. 59–80. Boca Raton, FL: CRC Press.

Table 5 Examples of soil organisms that can have negative impacts on human health.

Organism	Common name	Point of infection/ gateway	Disease name	Associated problems	Soil residency	Incidence	Geographic distribution
<i>Necator americanus</i>	Hookworm	Intestine	Ancylostomiasis	Chronic anemia, diarrhea, cramps	Periodic	1.2 billion/year (includes <i>A duodenale</i>)	Central and South America, southern Asia, Australia, Pacific Islands
<i>Strongyloides stercoralis</i>	Roundworm	Small intestine	Strongyloidiasis	Abdominal pain, diarrhea, rash	Permanent	100 million/year	Tropical, subtropical, and temperate regions
<i>Enterobius vermicularis</i>	Pinworm	Colon	Enterobiasis	Anal itching	Incidental	200 million total	Temperate regions
<i>Entamoeba histolytica</i>	Giardia	Intestine	Amebiasis	Diarrhea, dysentery, liver abscesses	Incidental	40 million	Worldwide
<i>Giardia lamblia</i>		Large intestine	Giardiasis	Diarrhea, abdominal cramps, bloating, fatigue, weight loss	Transient-incidental	500,000	Worldwide
<i>Dientamoeba fragilis</i>		Gastrointestinal tract	<i>D. fragilis</i> infection	Mild abdominal pain, gas, diarrhea	Unknown	2–4% of the population in developed countries	Worldwide
<i>Aspergillus</i> sp.		Respiratory, possibly through contaminated biomedical devices	Aspergillosis	Wheezing, fever, cough, allergic sinusitis, chest pain, shortness of breath	Permanent	1–2/100,000	Worldwide
<i>Coccidioides</i> sp.		Respiratory, sometimes trauma to skin	Coccidioidomycosis (Valley fever)	Flu-like symptoms, fever, cough, rash, headache, muscle aches	Permanent	15/100,000	Southwestern United States, northern Mexico, microfoci in Central and South America
<i>Trichophyton</i> sp., <i>Microsporum</i> sp., <i>Epidermophyton</i> sp.	Ringworm	Skin contact	Tinea corporis	Itchy, red circular rash with healthy-looking skin in the middle		Common	Worldwide
<i>Bacillus anthracis</i>		Respiration, skin trauma, ingestion	Anthrax	Ulcer w/black necrotic center, severe breathing problems, shock, nausea, fever, vomiting, diarrhea, abdominal pain	Periodic	Rare	South and Central America, southern and eastern Europe, Asia, Africa, the Caribbean, the Middle East
<i>Clostridium tetani</i>	<i>E. coli</i>	Skin trauma	Tetanus (Lockjaw)	Painful muscle tightening	Permanent	500,000 annual deaths	Worldwide
<i>Escherichia coli</i>		Ingestion	Diarrhea	Bloody diarrhea, abdominal pain, vomiting, fever	Incidental	5 million/year	Worldwide
<i>Clostridium botulinum</i>		Ingestion	Botulism	Vision problems, slurred speech, dry mouth, difficulty swallowing, muscle weakness	Permanent	Rare	Worldwide
<i>Clostridium</i> sp. (other than 2 above)		Skin trauma	Gas gangrene	Air under skin, blisters, fever, drainage, pain	Permanent	Common before antibiotics	Worldwide
<i>Rickettsia</i> sp.		Tick bite	Rocky Mountain spotted fever, other tick fevers and spotted fevers	Fever, nausea, vomiting, severe headache, pain, rash	Periodic	250 to 1200 cases/year in the United States	Worldwide

Table modified from Collier D and Brevik EC (2021) Soils and human health: Communication between soil scientists and health care providers. In Lal R (ed.), *The Soil-Human Health-Nexus*. 59–80. Boca Raton, FL: CRC Press.

Fig. 3 Examples of some soil pathogens. (A) Infective, third-stage filariform larvae (L3; center of picture) of *Strongyloides stercoralis* at 128 × magnification. L3 larvae are found in soil and can invade a human host by penetrating the skin. (B) A *Giardia* sp. protozoan is shown in the center of this scanning electron microscopic image. The circular lesion to its left shows where a *Giardia* sp. parasite was previously attached to the intestinal surface. (C) *Coccidioides immitis* at 600 × magnification, showing the chains of barrel-shaped arthrospores that are common to this organism. (D) A Gram-stained photomicrograph showing several rod-shaped Gram-positive *Bacillus anthracis* bacteria arranged in long strands. amounts of nutritious crops, a fundamental requirement for human health. However, they also represent indirect benefits for plant production. More recently the ways that soil microorganisms directly aid crop production have been explored in greater depth. Manipulating the soil microbial community found in the rhizosphere through inoculations with bacteria or fungi that promote plant growth has shown the ability to increase the quantity and nutritional quality of harvests (Brevik et al., 2020). Some of these inoculations are even able to improve crops when soil nutrient levels are low. These studies highlight the co-dependent nature under which plants and soil microbial communities have evolved, and the benefits hold true for a wide range of crops. Learning how to manage soil ecological systems appropriately will be an important part of achieving sustainable agricultural production and improving human health through soil-based benefits.

As we look toward the future, there are still many aspects of the soil organisms-human health nexus that need investigation. Most of the research to date has focused on soil microorganisms, investigating links between human health and soil macroorganisms has been largely overlooked. There is also a need to understand better the biological processes that underpin the improvements in yield and quality seen when the proper plant–soil microbe relationships are established, how exposure to soil microbes helps to build the human immune system, and links between the soil microbiome and human microbiome. Sequencing and metagenomics will likely assist in establishing these relationships. There is still an abundance of work to be done in this area.

Effects of soil pollutants – metals, organic chemicals, and radionuclides

Humans have released metals and metalloids (henceforth, metals for the purposes of this chapter) into the environment for thousands of years, but the rate at which metals have accumulated in soils and other environmental media at levels that lead to pollution accelerated rapidly during the Industrial Revolution. Although often associated with adverse effects on human and environmental health, metals are also quite important to human health; many of the elements essential to human life fall into these categories. Physiologically, metals take part in oxidation–reduction reactions in the human body, act as antioxidants or pro-oxidants, and play a role in relief from oxidative stress (Madeshiya et al., 2021). The challenge with metals is that the difference between deficient and toxic can be very small; in some cases this difference may be just a few tens to hundreds of grams per ha. When metals that are not essential for human health are present at toxic levels, they can react with the sulfhydryl enzyme and restrict

Table 6 Examples of pollution indices that have been used to provide information on the relationship between soil pollution levels and human or environmental health risks.

<i>Index</i>	<i>Basic measurement being made</i>
Contamination degree	The sum of the contamination factors for a given sample.
Contamination factor	The ratio between the content of a given metal and its background concentration.
Enrichment factor	Measures the impact of anthropogenic activity on soil trace element concentrations. It does this by comparing the ratio of the concentration of an element of interest to the concentration of a metal with a low variability of occurrence to the ratio of the background levels of the same two elements.
Geoaccumulation index	Evaluates soil contamination by a single trace element by calculating the logarithm of its concentration divided by 1.5 times its background concentration.
Modified degree of contamination	Degree of contamination divided by the number of analyzed elements.
Pollution load index	Determined by the number of times that the trace element concentrations in a soil exceed the background concentration
Single pollution index	Used to determine which trace element is the greatest threat in a given soil environment, calculated as the concentration of a trace element in the soil divided by its background value. Similar to contamination factor.
Sum of pollution index	The sum of all single pollution indices calculated for a given soil. Similar to degree of contamination.

cellular production by replacing essential metals on the enzyme's active sites (Ullah et al., 2020). Determining what level of metal accumulation in soil represents a threat is not straightforward. Several soil chemical properties, including pH, Eh (redox potential), organic matter content, clay content and mineralogy, and the presence of other ions, especially other metals, help determine the threat level for a given amount of metal in any given soil. To help researchers and policy makers address these differences between soils, several indices have been developed (Table 6).

There are several routes through which metals can be enriched in soils, including natural sources, industrial sites and wastes, e-wastes, traffic emissions, coal and fuel combustion residues, mining, paints, sewage, pesticides, fertilizers, and petrochemicals. Metals can affect several systems in the human body, including the blood, liver, brain, kidneys, skin, and lungs. Human health problems caused by metals include neurological degenerative processes (e.g. Parkinson's disease and Alzheimer's disease), cancers in the various body systems mentioned above, and osteoporosis (Brevik et al., 2020). One of the major concerns with metals in the environment is that they do not biodegrade over time. Once a metal is present in a soil, it has the potential to cause human and environmental health issues over very long periods of time.

A wide variety of materials fall under the heading of organic chemicals. Some are naturally occurring, such as petroleum and bitumen, but many of the organic chemicals that are major pollution concerns in the modern world are synthetic. Some of these synthetic chemicals were produced purposely (e.g. plastics, lubricants, fuels, solvents, herbicides, insecticides, and preservatives), but several are also unintended byproducts (e.g. polychlorinated dibenzo-p-dioxins (PCDDs or dioxin) and polychlorinated dibenzofurans (PCDFs)) of organic chemical synthesis. Many of these synthetic organic chemicals are highly resistant to microbial decomposition (Brevik and Burgess, 2013).

Among the synthetic organic chemicals, the particularly problematic formulations have become known as persistent organic pollutants (POPs). Chemicals classified as POPs are determined at meetings of the Stockholm Convention. The original list of 12 POPs was established in 2001 and became known as the 'dirty dozen.' Since then, nine more chemicals were added in 2009, one in 2011, one in 2013, three in 2015, two in 2017, and one in 2019 (Table 7). Some of the chemicals on the Stockholm Convention's list can still be used in limited applications, but some cause so many environmental problems that their use is now completely banned. In addition to the existing POPs, three chemicals are currently under review by the Stockholm Convention for possible future listing, Dechlorane Plus, Methoxychlor, and UV-328. Seventeen of the 29 POPs can be used as pesticides, and many of these have ended up in agricultural soils through pesticide applications. Health problems related to organic chemical use include diabetes, various cancers, cardiac failure, asthma, hepatic necrosis, dizziness, nausea, and headaches (Brevik et al., 2020).

Radionuclides in soil can also present health problems. They can be introduced to the soil through anthropogenic activities such as disposal of medical wastes, disasters such as Chernobyl (April 26, 1986) and Fukushima (March 11, 2011) or occur naturally. With many radionuclides the concern is uptake by crops, which pass the radioactive elements on to humans through the food web. A variety of cancers can be caused by exposure to this radiation. The decay process of radionuclides found naturally in soil also generates radon, which may accumulate in basements or other confined spaces with limited air movement and be inhaled, introducing radioactive elements to the lungs. Radon exposure combined with tobacco smoking is particularly problematic in the development of lung cancer.

Medicines from soil

Antibiotics

The most significant medical use of soil has been in the isolation of antibiotics from soil organisms, mainly bacteria and fungi. Antibiotics have been used for millennia, for example, ancient Egyptians and Greeks used various molds and plant extracts to treat

Table 7 Persistent organic pollutants (POPs) identified by the Stockholm Convention (SC). Some POPs can still be used for specific purposes as outlined in the SC.

Chemical	Year added	Source ^a	Annex in SC	Additional notes
Aldrin	2001	P	A	
Chlordane	2001	P	A	
Dichlorodiphenyltrichloroethane (DDT)	2001	P	B	DDT still used against mosquitoes in several countries to control malaria
Dieldrin	2001	P	A	
Endrin	2001	P	A	
Heptachlor	2001	P	A	
Hexachlorobenzene (HCB)	2001	P, IC, UP	A & C	
Mirex	2001	P	A	
Toxaphene	2001	P	A	
Polychlorinated biphenyls (PCB)	2001	IC, UP	A & C	Has specific exemptions under Annex A
Polychlorinated dibenzo-p-dioxins (PCDD)	2001	UP	C	
Polychlorinated dibenzofurans (PCDF)	2001	UP	C	
Alpha hexachlorocyclohexane	2009	P	A	No exceptions or acceptable uses
Beta hexachlorocyclohexane	2009	P	A	No exceptions or acceptable uses
Chlordecone	2009	P	A	No exceptions or acceptable uses
Hexabromobiphenyl	2009	IC	A	No exceptions or acceptable uses
Hexabromodiphenyl ether, heptabromodiphenyl ether	2009	IC	A	Can be used in accordance with the provisions of Part IV of Annex A
Lindane	2009	P	A	Human use for control of head lice and scabies as second line treatment
Pentachlorobenzene	2009	P, IC, UP	A & C	No exceptions or acceptable uses
Perfluorooctane sulfonic acid, its salts and perfluorooctane sulfonyl fluoride	2009	IC	A & B	Acceptable purposes and specific exemptions in accordance with Part III of Annex B, amended 2019
Tetrabromodiphenyl ether, pentabromodiphenyl ether	2009	IC	A	Has specific exemptions under Part V of Annex A
Technical endosulfan and its related isomers	2011	P	A	Exemptions for crop-pest complexes in accordance with the provisions of part VI of Annex A
Hexabromocyclododecane	2013	IC	A	Expanded and extruded polystyrene in buildings in accordance with the provisions of part VII of Annex A
Hexachlorobutadiene	2015	IC, UP	A & C	No exceptions or acceptable uses, added to annex C in 2017
Pentachlorophenol and its salts and esters	2015	P	A	Pentachlorophenol for utility poles and cross-arms in accordance with the provisions of part VIII of Annex A
Polychlorinated naphthalenes	2015	IC, UP	A & C	Can be used for production of polyfluorinated naphthalenes, including octafluoronaphthalene
Decabromodiphenyl ether	2017	IC	A	Exemptions for certain uses in vehicles, aircraft, textiles, additives in plastic housings etc., polyurethane foam for building insulation
Short-chain chlorinated paraffins	2017	IC	A	Allowed as additives in transmission belts, rubber conveyor belts, leather, lubricant additives, tubes for outdoor decoration bulbs, paints, adhesives, metal processing, plasticizers
Dicofol	2019	P	A	No exceptions or acceptable uses

^aP – pesticide, IC – industrial chemicals, UP – unintentional production/by-products.

infections. However, it was not known until the late eighteenth century that the infections were caused by bacteria. Penicillin was the first antibiotic to be discovered from the soil-borne fungus, *Penicillium notatum*, but at the time the term ‘antibiotic’ had not been coined. Penicillin was isolated by Sir Alexander Fleming in 1929 by accident on a culture of *Staphylococcus* on which *P. notatum* landed and created bacteria free zones. The antibiotic penicillin was mass produced in the early 1940s in the USA based on a process developed in Oxford, UK, and used widely by 1944 to treat troops for infections. Sir Alexander Fleming, Ernst Boris Chain and Sir Howard Walter Florey received the Nobel Prize in Physiology or Medicine in 1945 for their work on penicillin.

Selman Waksman was the first to coin the term antibiotic in 1943. In the 1940s, Waksman and his team at Rutgers University isolated several inhibitory compounds (actinomycin, neomycin and streptomycin) from *Actinomyces* and *Streptomyces* spp. (of the phylum *Actinobacteria*). These are prokaryotic organisms that are Gram-positive, filamentous and mainly aerobic and saprophytic bacteria that produce spores. Waksman’s team went on to discover over 20 inhibitory substances from *Actinomycetes* by 1944.

Fig. 4 Magnified image of a culture of *Streptomyces* sp. bacteria. Note the branching filamentous hyphae, abundant aerial mycelia, and long chains of small spores. These features are characteristic of all *Streptomyces* spp. Photo courtesy of the Centers for Disease Control and Prevention, image ID# 2983.

Waksman, (1952) found that some microbes compete with one another for survival by secreting secondary metabolites as a chemical defense (for example antibiotic, antifungal, immunosuppressant, anti-tumor and antihelminthic products) to gain a competitive advantage in the soil ecosystem (Ratnaddass et al., 2006). The production of antibiotics and other metabolites by *Actinobacteria* appears often to be controlled by diffusible hormones produced during the filament forming part of their life cycle.

The complex secondary metabolites produced by *Actinomycetes* account for over two thirds of all known antibiotics, of which the majority is produced by *Streptomyces*. Some *Streptomyces* (Fig. 4) species produce a single antibiotic, but others produce a range of different compounds and compound classes (Barka et al., 2016). The soil is a reservoir of potentially new antibiotics because bacteria are continuously developing new ones to resist new stresses. Until recently, however, the physiology and genetic make-up of only a few bacteria have been studied because most (>99%) cannot be cultured in the laboratory. Now advances in genomics methods can enable the physiology and genetics of microbes that cannot be cultured to be determined. A recently discovered (2014) soil bacterium, temporarily known as *Eleftheria terrae*, was found to produce a new antibiotic, teixobactin. It has been found to be effective against multidrug-resistant bacteria such as *Staphylococcus aureus* and *Mycobacterium tuberculosis*. Another new group of antibiotics known as malacidins was discovered recently (2018) from *Streptomyces albus* after examining 2000 soil samples. The great advantage of the malacidins is that they are also effective against multidrug-resistant pathogens. When tested against *S. aureus* malacidins were found to be effective. Soil fungi, for example the cephalosporin group, are also major sources of antibiotics. The successful immunosuppressant cyclosporine is derived from the fungus *Tolypocladium inflatum*.

Several antibiotics derived from soil bacteria are widely used as chemotherapeutic drugs such as the anthracyclines Daunorubicin and Dexorubicin, which are produced by *S. peucetius*. Actinomycin D, which was one of the first antibiotics discovered, is commonly used to treat many types of cancerous tumors. The National Cancer Institute (Bethesda, Maryland) launched an effort in 2015 to encourage research into natural products from the environment such as from soil as a source of new drugs.

The need to find new antibiotics is critical because of the increase in resistance of many pathogens to several currently used antibiotics. A major cause of this resistance has developed from the release of antibiotics to soil and water through applications of human and animal waste to soil and water. These exogenous antibiotics affect soil microorganisms by changing their enzyme activity and ability to metabolize various sources of carbon. Furthermore, the mixing of exogenous bacteria with indigenous antibiotic-producing bacteria (Wellington et al., 2013) can result in horizontal gene transfer that produces antibiotic-resistant genes (ARGs). The ARGs relate to agricultural and human activities in several ways, one of which is their incomplete metabolism in humans and animals.

Clays

The ancient Greeks used Lemnos earth, a mud most probably composed of clay, for skin problems and snake bites. The phyllosilicate clays have had a long history of medicinal use because of their capacity for adsorption and absorption, and surface charge. The clays used in pharmaceuticals include smectites such as bentonite, palygorskite (attapulgite), kaolinite and talc, which have large specific areas with strong adsorptive and absorptive capacity, rheological properties, are chemically inert and have little or no toxicity. They can remove secretions, contaminants and toxins from the skin and adsorb aflatoxins, which are naturally occurring carcinogenic mycotoxins, toxic secondary metabolites produced by several *Aspergillus* species (commonly known as molds) and found in all soils. Clays used for gastrointestinal therapy are palygorskite (a magnesium aluminium silicate) and kaolinite because of their large specific area and sorption capabilities. These clays are used to treat diarrhea because they absorb water and gases and can absorb toxins, bacteria and viruses.

Otto and Haydel (2013) examined the antibacterial properties of natural clay mixtures in vitro and tests on their samples showed that *Escherichia coli* and methicillin-resistant *Staphylococcus aureus* (MRSA) were killed in 24 h. They considered that the antibacterial properties are due to adsorbed ions on the clays, namely Fe^{2+} , Cu^{2+} and Zn^{2+} . Brunet de Courssou treated the Buruli ulcer caused by a necrotizing flesh-eating mycobacterium, *Mycobacterium ulcerans*, with two French green clays. One of the clays killed the bacterium, which is endemic in Central and West Africa. However, the mechanism by which the clay minerals inhibit bacterial growth remains unknown.

The future

Humankind has learned much about the links between soil and human health, starting with experiential, trial and error approaches early in our history to the complex, carefully planned scientific experiments that are run today. However, true scientific study of the relations between soil and human health did not really start until about the 20th century, and we still have much to learn.

The impacts of soil properties and processes on human health are due to complex interactions that are difficult for any single discipline to study adequately and do not translate well to the use of traditional approaches that isolate a single variable to determine how it affects the overall system. It has been conclusively demonstrated that similar levels of, for example, soil contamination by cadmium at two different locations can have two very different outcomes in terms of human health (Brevik and Burgess, 2013). This is because factors such as soil physical and chemical properties influence cadmium availability to plants, and through that just how the contamination impacts human health. Simply isolating cadmium as a variable and seeing how the system reacts is not sufficient. Several indices have been developed to evaluate the health risk associated with metals found in soil, and these are better than just using total contaminant concentration (Brevik et al., 2020). However, their use assumes that the soil itself is the only factor determining the effects on health. Human diet, for example, has also been shown to play a role. Returning to the cadmium example above, the diet in one location was deficient in iron and zinc compared to the other, and cadmium retention is increased 15 times in those with iron and zinc deficient diets compared to those with diets that are not deficient (Brevik and Burgess, 2013).

As we seek to understand complex interactions new models and statistical techniques will be required, and we will need to learn from other fields that work with similar challenges. There are several approaches utilized in modern epidemiology that are able to account for multiple variables but are not typically used in soil science, including causal diagrams, marginal structural models, and propensity score methods (Brevik et al., 2021). Epidemiologists also deal with environmental exposures, just as soil scientists and others with an interest in soil and human health links do, providing promise that techniques that work for epidemiology may also work in soil and human health research. Omics approaches in biology are another good example that could be applied to the study of soil pathogens and the broader soil microbial community. As we look to the future, it will be important to learn from related fields and investigate the applicability of their techniques to address soil and human health challenges.

Multiple disciplines engage in the knowledge necessary to address the links between soil and human health holistically. Agronomists, biologists, crop scientists, epidemiologists, geographers, geologists, lawyers, medical doctors, public health officials, sociologists, soil scientists, and others have roles to play. The disciplines in this list are diverse, do not all speak the same professional language, not all of them typically work together, and they do not communicate using the same professional outlets. Finding ways to facilitate communication and cooperation between these diverse professional groups will be a key part of moving our knowledge of soil and human health links forward, and how to implement that knowledge effectively.

Another challenge we face is how to raise awareness concerning the importance of soil to human health among the general public, health agencies and governments to initiate a preventive approach to maintaining healthy populations. Research areas that are perceived as important receive higher levels of funding than those that have less recognition (Brevik et al., 2020). Several options for developing this recognition have been suggested, including using social marketing or social media platforms to build recognition of soil and human health issues by connecting them to concepts such as soil health or soil security (Brevik et al., 2020). These are concepts that already have a level of acceptance among non-soil scientists or are connected to concepts such as energy, food, and water security that have wider acceptance. In addition, they have direct, easily understood links to soil and human health.

So, to understand soil and human health links adequately we need to find ways to account for changes in multiple variables that are all acted on by different parts of the overall environment, from air to biota to soil and continuing to water. This will involve approaching scientific study of the problems encountered in non-traditional ways. We need to engage multiple disciplines that have not traditionally worked together and facilitate communications between them; each disciplinary expert needs to have full understanding of what the others are saying and be able to work with them at a high level. Beyond this, we need to engage with the public and communicate the importance of what is being done to build support for research on soil and human health. This is truly a Grand Challenge! However, the rewards for success will also be substantial. Many of the connections between soil and human health can lead us to better nutrition, avoidance of pollutants, enhanced allergy resistance, and the like. Therefore, if we can improve our knowledge of the complex links within the soil–human health nexus that should allow us to improve health with less reliance on, for example, medications and medical procedures, in other words, to enhance our ability to practice preventive medicine.

Abstract

Soil science education takes place in the formal classroom, laboratory, and extension and outreach settings. It can be provided by professionally trained teachers in schools and universities, individual scientists reaching out to the public, or professional societies looking to expand knowledge of the discipline. Regardless of the form, setting, or identity of those delivering this education, it is important to understand that teaching involves more than just the delivery of discipline-specific content. Soils knowledge is used to address a wide range of modern problems. Inter- and trans-disciplinary thinking, communications, and interpretative skills are also needed to address global challenges.

Key points

- Why soil science?
- Why we need to change?
- To teach does not mean to educate.
- How should we educate to create soil preservation values that move us towards sustainability?
- How should we change soil science teaching to guarantee life on the planet?
- Why start at the primary education level?
- What do we propose to do?

Introduction

There are many reasons to educate people in soil science. Without fertile soil, there are no plants or animals for food, no clean water to drink, no oxygen to breathe, that is, no life or development to reach or sustain. Furthermore, soil provides fiber, fuel, and building materials, all of which make soil essential to human health and wellbeing (Brevik et al., 2019). Soil is the natural habitat of an immense number of organisms and microorganisms, and therefore, a source of biodiversity; it filters, recirculates, and defines the distribution of water; it is a waste deposit; and an excellent catalyst in green chemical reactions and therefore a real path to reduce pollutants in the environment (Reyes-Sánchez, 2012a). Soil is a natural resource, but also a social, economic, cultural, political and patrimonial good of mankind (Reyes-Sánchez, 2018). Soil loss influences poverty, displacement, inequality, violence, and injustice as a result of famine; therefore, it is essential that we study and preserve soil (Reyes-Sánchez, 2012b). Education is very important in the preservation of soil, because “that which is not known is not valued and therefore will not be protected or cared for” (Fig. 1).

Soil science education takes place in multiple ways, including formal classroom settings with a variety of delivery methods, internships, outreach to groups ranging from children to adults, and many other modes (Brevik et al., 2020; Field et al., 2017).

Fig. 1 The importance of soil to all.

Education can be provided by professionally trained teachers, professional societies, or others who have an interest in the topic. In addition, delivery modes change over time along with new technologies and the interests and experiences of students and teachers. The COVID-19 pandemic also created change in educational approaches to soil science education (Mahler et al., 2021).

This chapter will explore important concepts in soil science education, some of the more common modes of education delivery, groups that soil science educators commonly reach out to, and soil science professional groups that engage in public education. There will also be some discussion of ways that the COVID-19 pandemic affected soil science education and outreach, and how that may lead to future changes.

Important concepts in soil science education

All disciplines have a certain core body of knowledge that forms the unique foundation of that discipline. Churchman (2010) identified five subdisciplines that form the foundation of soil science: (1) pedology, (2) soil biology, (3) soil chemistry, (4) soil mineralogy, and (5) soil physics. If these subdisciplines are accepted as being essential to understand soil science, training in them and the supporting coursework to understand them is essential in soil science education (Brevik et al., 2020).

However, soil science education needs to go beyond this. Modern soil science has become interdisciplinary and even transdisciplinary in its nature. This makes it necessary to expand our vision for soil science education to include coursework that provides inter- and trans-disciplinary values, thoughts, procedures, and actions that will allow graduates to address social, economic, legal and environmental problems to achieve true development for all (Reyes Sánchez, 2016). Another way to address this is through academic-industrial partnerships that expose students to complex real-world problems as a way to develop the students' critical thinking skills and expose them to a variety of perspectives (Field et al., 2017).

Understanding the complexity of soil science and the issues it addresses requires understanding that soil is itself a system. Therefore, if we want to explain adequately the world in which soil scientists work, which is complex, integrated, interdependent, interdisciplinary, and transdisciplinary, our teaching should also mirror this. It needs to include the fields of applications and experiences that we seek to exert both within the school context, from preschool to doctorate, as well as in broader society.

Modes of educational delivery

As early as 1657, Juan Amos Comenius identified the need to teach using a comprehensive and unitary educational system. This system would provide a logical structure that allowed teachers to facilitate satisfactory learning, which in turn would influence thinking and transform it for the benefit of the individual and society (Comenio, 2000).

Science, including soil science, needs to be taught by guiding students to think and work as scientists, whether this involves teaching in the classroom, the field, or the laboratory. Whether addressing children, teenagers, postgraduate students, or other stakeholders, this needs to be congruent with the concepts and methods of science. Questions need to be chosen that define progressive hypotheses or research questions that address the problem that we intend to solve, with methods then proposed to solve the problem. Therefore, science teaching as a scientific activity should have 'a goal', 'a method', and 'an application field' appropriate to the school context that allows students to arrive at answers to the research problems that arise from observation and definition (Reyes-Sánchez, 2018).

A wide array of delivery modes are available for soil science education. The most common delivery methods are traditional lectures, laboratory analyses, and field trips (Krzić et al., 2018). Other approaches that are documented in the soil education literature include soil judging (Smith et al., 2020), online delivery of course materials (Ulery et al., 2020), open-source textbooks (Moorberg, 2020), and flipped classrooms (Ramírez II et al., 2022). Any of these can be formatted to provide the scientific teaching approach advocated above, but they have to be developed with that goal in mind, and it has been suggested that active learning approaches are the most effective (Smith et al., 2020).

The COVID-19 pandemic that began in 2020 represented a serious challenge to soil science education. Teachers around the world were forced to move their classes to distance delivery at very short notice, and in many cases this approach to soil science classes had never been given serious consideration (Mahler et al., 2021). Delivery modes prior to the COVID pandemic covered all options previously discussed, ranging from traditional lectures to highly active learning approaches, and each of these presented their own challenges. The journal *Natural Sciences Education* recently published a special issue that presented and analyzed the approaches taken by several soil science teachers to address the COVID-19 emergency (Mahler et al., 2021). Students generally indicated that they preferred face-to-face activities to the distance learning options (Wyatt, 2021), and they were less engaged in their learning. Synchronous approaches did show more engagement with the subject than asynchronous approaches (Walker and Koralesky, 2021). Many instructors developed online materials during this time that they plan to incorporate into future classes, albeit not always used exactly as they were during the COVID-19 emergency, because they feel these materials will enhance their future classes (Brown and Krzić, 2021). It will be important to consider carefully the lessons learned during COVID-19 and how they can help improve and expand soil science education in the future (McCauley, 2021).

Outreach by professional groups

Many professional soil science societies engage in educational outreach efforts at multiple levels. This section will not attempt to provide a comprehensive listing of these professional groups and their efforts, but will provide some examples.

International Union of Soil Sciences

The International Union of Soil Sciences (IUSS) has called for explicit recognition that fertile soil is essential for all agricultural practices that guarantee food security, and that soil supports all human, social, and ecosystem functions (IUSS, 2002). Consequently, the IUSS called on everyone to commemorate World Soil Day every December 5. On December 5th, 2015, the IUSS launched the "International Decade of Soils 2015–2024" (IUSS–IDS) with the Vienna Declaration (<https://www.iuss.org/international-decade-of-soils/>). The two main objectives of IUSS–IDS are "Stop land degradation as the most insidious and underestimated challenge of the 21st century, and direct the main focus of all activities on school age children and young adults who will be teenagers and young adults in 10 years time" (Hom, 2015). Therefore, interdisciplinary soil science education, awareness, and outreach is a fundamental goal of the IUSS, both to face the environmental challenges of today and to be able to confront those that will occur in the future.

The IUSS has addressed this with many recent educational projects, including a children's book project that was run jointly with the Food and Agriculture Organization of the United Nations (FAO) in 2020 (<http://www.fao.org/world-soil-day/bookcontest/en/>) and 2021 (<https://www.fao.org/world-soil-day/concurso-de-libros/en/>), publishing the book "Soil Science Education: Global Concepts and Teaching" (Kosaki et al., 2020), and "The IUSS Goes to the School" education project (<http://www.iuss-goes-to-school.org.mx/>). The IUSS website for this education project provides links to books, videos, experiments, and other educational resources to help children learn about soil. Some of these resources are available in multiple languages. The IUSS financially supports the education and dissemination initiatives of its national soil science societies through its stimulus fund program.

Latin-American Soil Science Society

The Latin-American Soil Science Society (SLCS; Sociedad Latinoamericana de la Ciencia del Suelo) has collaborated with its member countries since 1987 developing the education project "Thus are the Soils of my Nation" (<https://www.slcs.org.mx/index.php/educacion-y-ensenanza/asi-son-los-suelos-de-mi-nacion>), a project to introduce students to the soils found in their home country. This is done using children's books, plays, games, educational aids, and training for teachers. "Thus are the soils of my Nation" works with primary school children using the school orchard as the center of their activities to achieve the main

objective: “that children understand that the soil is an indispensable natural resource to preserve life on Earth” (<https://www.slcs.org.mx/index.php/fotos>). The School Orchard Program in educational centers for the development of environmental and sustainable competencies of teachers and students is promoted by teachers, national soil science societies, FAO, and NGOs (<https://educacio-valencia.es/es/proyectos/el-huerto-escolar-como-herramienta-educativa/>) (<https://www.bodeninfo.net/projekte/bodenmacht-schule/>) (https://www.euskadi.eus/contenidos/documentacion/inn_doc_ed_ambiental/es_def/adjuntos/800001c_huerto_escolar_c.pdf; <https://lifelab.org/> <https://edibleschoolyard.org/>).

An indispensable part of “Thus are the soils of my Nation” is the “Symposium of Educative Innovations on Teaching and Learning Soil Science” as a permanent space open to the expression and presentation of children’s research within the congresses of the Latin American Society of Soil Science (<https://www.slcs.org.mx/index.php/educacion-y-ensenanza/simposio-de-innovaciones-educativas-en-la-ensenanza-de-la-ciencia-del-suelo>). Another important part of this Latin American collaboration is the multi-language glossary of soil science terms (<https://cit.iec.cat/DMCSE/default.asp?opcion=0>).

Soil Science Society of America and others

The Soil Science Society of America (SSSA) has extensive resources for kindergarten to twelfth grade teachers (K–12 teachers) at <https://www.soils4teachers.org/>. These include the ability to ask a soil scientist a question, a soil science glossary, pre-developed lessons and activities that are aligned with USA education standards, posters, webinars, videos, and other materials. The SSSA also developed monthly educational videos as part of the Year of Soils in 2015, and these can be found at <https://www.soils.org/iys/monthly-videos/>. Many of these SSSA resources have been available for over a decade as of 2022 and new resources continue to be added.

Some other worldwide education resources available from professional societies include the British Soil Science Society materials for primary schools (http://www.soil-net.com/downloads/soilsafari_teachernotes.pdf) and education supports of the French Association pour l’Etude des Sols: <https://www.afes.fr/ressources/bibliotheque> or FNEassociation (<https://www.fne-aura.org/notre-offre/rhone/nos-kits-pedagogiques-a-decouvrir/>).

Museums as educational spaces

Important educational efforts have been made worldwide through museums with outstanding collections of soil profiles and their corresponding descriptions (Table 1).

Table 1 Museums with soil profile collections.

Country	Museums
Argentina	Universidad Nacional de Río Cuarto, Instituto Nacional de Tecnología Agropecuaria.
Australia	The University of Sydney (Australian Technology Park).
Austria	University of Vienna.
Belgium	KU Leuven.
Brazil	Universidade Federal de Lavras, Universidade Federal de Roraima, Universidade Federal de Santa Maria.
Canada	University of Alberta, University of British Columbia, Great Lakes Forestry Center (Ontario).
Colombia	Museo de Suelos Ciro Molina Garcés, Museo de Suelos Instituto Geográfico Agustín Codazzi.
China	China Soil Museum; The Modern Soil Monolith Exhibition Center.
Estonia	Soil Museum Estonian University of Life Sciences.
Germany	Museum für Bodenschätzung in Eickendorf (Börde).
India	Kerala Forest Research Institute.
Indonesia	Museum Tanah (Bogor Soil Museum).
Japan	Natural Museum of History and Science, Natural Resource Inventory Museum, Tsuchino-Yakata, Hokkaido.
Netherlands	World Soil Museum, Wageningen University, VU University, Rijksuniversiteit Groningen, HAS Hogeschool, VHL University of Applied Sciences, Museonder, Geologisch Streekmuseum ‘de IJsselvallei’.
Peru	Museo de Suelos.
Russia	Vasily Dokuchaev Museum of Soil Science, St Petersburg; Williams Museum of Soil and Agriculture, Moscow.
Spain	Universidad de Murcia, Universidad de Granada, Insititu Cartogràfic de Catalunya.
Taiwan	National Taiwan University, Research Institute.
Thailand	Soil Museum Bangkok.
United Arab Emirates	Emirates Soil Museum.
United Kingdom	Cranfield University, Natural History Museum, London
United States of America	Kansas State University, University of Idaho, Texas A&M, Virginia Tech, West Virginia University, University of Georgia, Smithsonian’s National Museum of Natural History (2008–2009), Cayuga Nature Center (NY), Diné College (AZ), American Museum of Natural History (NY), St. Louis Science Center.
Uzbekistan	State Research Institute of Soil Science and Agrochemistry.

Groups that soil science educators interact with

Soil science education can take many forms and be done with many different groups of students. These range from children in primary and secondary schools to undergraduate and post-graduate students in colleges and universities. But it also includes farmers and ranchers, in settings often referred to as extension, and outreach to the public. Citizen science projects have become popular over the last decade, and several that involve soils have been undertaken (e.g., Sandén et al., 2020). In this context, the FAO launched the Global Soil Doctors Programme in 2020. This is a farmer-to-farmer training initiative being implemented at the global level on a voluntary participation basis and centers attention on the importance of soil as a vital resource for farmers, policy makers, development planners, agricultural extension workers, NGOs, private sectors, and stakeholders (<https://www.fao.org/global-soil-partnership/pillars-action/2-awareness-raising/soil-doctor/es/>). This is being done in collaboration with soil scientists, soil science societies, and universities, with an emphasis on Bangladesh, Malawi, and Mexico (https://www.fao.org/global-soil-partnership/resources/highlights/detail/en/c/1470466/?fbclid=IwAR0qmaCfdaiWFbDlG_GSPpWj6qTqYpzGb3IY0ofhokzCYB0MlqmBqbqR8VA).

The importance of primary and secondary education

*Like the soil, no matter how rich it may be, cannot bear fruits if it is not cultivated
The mind without cultivation cannot produce either*
Seneca

According to the main goals of the IUSS “International Decade of Soils: 2015–2024”, the IUSS aspires to be a leader in the process of educating our future scientists, as well as in generating public awareness of soil sustainability (Horn, 2015). Educating children and teenagers is a priority for the IUSS because the future of soil, and therefore of life on the planet, will be in their hands. The responsibility to ensure that children and teenagers understand the value of the soil resource, and commit to its preservation, is ours. We need to teach children and teenagers why the soil is important in their daily lives.

To teach is not the same as to educate

*“It produces an immense sadness to think that nature speaks
while humankind does not listen to her”*
Victor Hugo

When UNESCO (1971) defined environmental education as “the cognitive process of recognition of values and clarification of concepts to promote the necessary attitudes to understand and appreciate the interrelationships between man, his culture, and his biophysical environment”, it made clear the intrinsic relationship between the education process and human construction of environmental awareness and culture. However, lack of knowledge about the value that natural resources in general, and soil resources in particular, have in our lives has not encouraged citizens to create a culture of environmental preservation that is manifested in their daily actions. The increased urbanization of society, and its detachment from the food production process, means that a significant proportion of the human population lacks a fundamental understanding of soil as an invaluable resource, its functions, and the benefits and services (including food production) received from soil. Therefore, it is important to build citizen awareness about the value of the soil resource (Brevik et al., 2018).

Teaching is not the same as educating. Educating entails the explicit and implicit formation of values that emotionally and cognitively implant the information transmitted, thus making possible the progressive formation of a conscience that in the medium- and long-term builds, little by little, a culture of environmental consciousness (Reyes-Sánchez, 2012a). It is about the contents of all we teach being taught with the goal of preserving the soil for sustainability.

When we teach soil science, we are transmitting basic and specialized information at various levels. We teach how to use that knowledge in theory and practice and how to use that information for interpretations, corrections, and projections. Unfortunately, that does not create an environmental consciousness or culture for preservation that supports the soil’s sustainability. Knowledge accumulates when we teach and it is not possible to transmit what you do not know. However, public awareness requires education. To reach a position where soil preservation becomes important, we need to do more than teach people about soil. We need to educate them to preserve the soil resource because it is indispensable for life itself. To do this it is necessary to explain to people why soil is essential for them and why soil loss affects us all, regardless of the social class to which we belong and regardless of the location we live in (rural or urban, continent we live on, etc.). “Soil preservation is a common good of humankind” (Declaración de Mar del Plata, 2012).

How do we educate to build values that ensure respect for the soil?

*“Educating is more difficult than teaching
To teach you only need to know, but to educate, you need to be”*
Albert Einstein

According to the pedagogical perspective of Antón Makarenko (1959), the teaching of science through education must harmonize social interests with the particular interests that students have, involving them in the search for solutions to everyday problems. For Arca et al. (1990), learning science implies learning to change the ways one sees phenomena, reasoning, speaking, and emotions; taking account of these simultaneously. Gómez and Reyes-Sánchez (2004) argue that education to preserve natural resources to advance towards sustainability is an objective that goes beyond one subject or a set of them in the curriculum. They posit that education is not about reproducing actions focused on techniques, but rather an invitation to debate and reflect on the type of technology and social organization that allows people to live in harmony with each other and the natural environment. Creating environmental awareness in society involves education to change individual and collective behaviors (something done with social marketing; Brevik et al., 2018). This implies a transformation that affects the personal lifestyle as seen in consumption, health, civic attitudes, and equality, and prepares whoever is educated in this way to exercise democracy as a way to create the same scale of values. By teaching and learning science in this way, we form values, we form a consciousness, and we build a preservation culture (Fig. 2).

All these approaches indicate that we require a change of perspective globally. Although science can help, pollution, devastation, degradation, and loss of soil resources are not problems that can be solved technologically given the prevailing values of competition, lack of solidarity, exclusion, uniformity, or hierarchy, governed by the global market (Gómez and Reyes-Sánchez, 2004; Gutiérrez, 1995; Gil and Vilches, 2005; UNESCO, 2009).

However, we can pretend to teach values as simple theoretical entities and even impose them from a decontextualized and rote learning perspective, in which the purpose is repetition, oral or written, as a synonym for learning. This is neither pedagogically nor environmentally desirable. What is needed is to inform humans with the knowledge and awareness that allows them to assume different ways of using soil and new forms of coexistence between humans and the soil resource (Reyes-Sánchez, 2006).

Fig. 2 Interdisciplinary soil science education has no borders and neither does its teaching.

What should we do?

*We propose to educate in soil science on a planet that is a natural system
and work together as a team to put the gaze
and concern of the world on soil*

The following points are proposed to create an enhanced global level of soil education: (a) work with children and teenagers to educate them about and create an awareness of soils and their importance, (b) open the professional soil science curriculum to inter- and trans-disciplinary research and teaching, and (c) provide adequate support and training to those who teach soil science.

Working with children

We, today's soil scientists, can decide what soil science knowledge to impart, how, and to whom. It is up to us to decide if we should continue to limit the teaching of soil science to highly specialized professionals, or if we are willing to make a personal commitment to make soil education accessible to students who are children and teenagers who are practically blank pages, to provoke their interest, enthusiasm, and love for soil (Reyes-Sánchez, 2020). This would involve researchers and university professors working with teachers at pre-university levels to create a new paradigm in the teaching of soil science. As shown in the "Outreach by professional groups" section, many soil scientists are already taking steps in this direction. This is important work that needs to continue.

Opening the professional soil science curriculum to inter- and trans-disciplinarity

The disciplinary subdivisions of science, including soil science, have their value. But we cannot fail to recognize that in reality there are no simple or isolated problems, but many complex problems that face our modern world. Therefore, it is not possible to address these problems only from the isolated view of the disciplinary divisions. We need to work to build, through inter- and trans-disciplinary integration from various fields of knowledge, specialized knowledge in soil science that allows us to address complex problems and propose viable solutions. This includes multicausal and interdependent perspectives. It is important for the modern soil scientist to be exposed to fields ranging from biology, chemistry, and physics to communications, economics, the law, and sociology (Brevik et al., 2020).

The United Nations Sustainable Development Goal (SDG) 4 is "Ensure inclusive and equitable quality education and promote lifelong learning opportunities for all". An interdisciplinary practice and teaching of soil science could help construct an education that advocates the search for solutions that are culturally and ethically acceptable, economically feasible, energetically desirable, and environmentally respectful of the balance of ecosystems as the foundation of a socially responsible science. This would environmentalize¹ all knowledge through a continuous methodological process that allows both building the knowledge that children and teenagers have from the simple to the complex, and pedagogically organizing all actions in an equally processual way. This would establish stages of knowledge construction, with increasing levels of complexity in terms of relationships and interrelations, and thus closer to a true perception of reality. Approaching soil in an inter- and trans-disciplinary way is important in understanding that soil is itself a system. When we talk about development goals, we talk about the development and sustainability of natural and social systems. These systems are open and dissipative, in a constant state of change (Reyes-Sánchez, 2012b).

Provide adequate support and training to those who teach soil science

During the Tbilisi in 1987, Rio in 2000, and Johannesburg in 2002 summits, both the UN and UNESCO emphasized the importance of training teachers whose activities and decisions significantly influence the education of future citizens and prepare them to meet the challenge of responding to present and future problems. Achieving this implies empowering and sensitizing people so they recognize there are no pre-established rules that are always valid and they know how to make decisions that will lead to soil preservation. It also implies ensuring that people can change their behaviors according to circumstances, publicly defend their opinions and recognize those of others, engage in dialogue, and be able to negotiate (Gómez and Reyes-Sánchez, 2004). Therefore, among the primary characteristics to develop in teachers so that they can transfer them to students are the development of values and attitudes. In this way future citizens will be capable of making and participating in all kinds of decisions with solid arguments based on knowledge and manifested firmly through reflective attitudes, but above all, based on analysis carried out in the light of the values formed.

Concluding statements

Education for soil sustainability requires that it is participatory, effective, multicultural, dialogic, democratic, investigative, interdisciplinary, and activist. It is important to teach children, teenagers, and adults not just to be content with knowledge, but also how to be competent workers, reflective citizens, social critics, and agents of change (Reyes-Sánchez, 2020). This will be required if we are

¹A methodological process that approaches the environmental problems in a cognitive and interdisciplinary way through education and the practice of science with the objective of building a preservation culture and conscience by providing models for the management and exploitation of natural resources towards the development for all (Reyes-Sánchez, 2012b).

to have a society committed to sustaining the soil resource. It will be important for soil scientists, educational institutions, and professional societies to commit to such an educational vision. The national soil science societies in countries around the world can join with each other and the IUSS to train future citizens of the world in the knowledge and environmental awareness necessary to achieve this.

Abstract

Soil often plays a key role in landscape planning. However, there are some key limitations to conventional approaches for incorporating soil data into planning models. The separation of soil and land-use layers in conventional planning maps has led to a systemic misunderstanding of the complex socio-ecological relationships that drive processes like land degradation and climate change induced migration. Failed conceptual models for how to imagine the relationship between soils and human environments should lead us to reconsider the way soils are made an object of planning in the 21st century.

Key points

- The desire to use soil as a resource shapes the way it is understood empirically.
- Soil-based disciplines are epistemologically diverse and produce soil knowledge that is not always mutually compatible.
- Layer-based planning maps traditionally obscure the socio-ecological relationships that are key to soil health and conservation
- More effective approaches to incorporating soil knowledge into planning processes will require each discipline to rethink its methods and values

Introduction

The majority of the world's soil resources are degraded. In technical terms, they are in fair, poor, or very poor condition according to the Food and Agriculture Organization's most recent inventory (Food and Agriculture Organization (FAO) and Intergovernmental Technical Panel on Soils (ITPS), 2015). Roughly half of all people on Earth live in landscapes degraded by erosion, salinization, compaction, acidification, chemical pollution, or subsidence and by 2050 between 50 and 700 million people will be forced to migrate as climate change further erodes the material basis of life in arid and low-lying regions (Montanarella et al., 2018). 20th century modes of urbanization and agriculture have had profound consequences for the world's soil resources. The realization that these consequences are best described as "degradation" should be cause for some concern, as the presence of anthropogenic soils are now a plausible stratigraphic indicator for our planetary geologic epoch (Certini and Scalenghe, 2011).

Landscape planning is a field that cuts across many of the processes that drive soil degradation. Processes such as urbanization, deforestation, and agriculture are all key concerns of landscape planning. However, the scope and scale of these concerns makes expertise in the subject highly distributed. There are environmental planners, landscape architects, geographers, land-use planners, foresters, civil engineers, urban ecologists, and landscape ecologists, all of whom claim some expertise in what could be summarized in a word: land. Rather than something intrinsic to the terrestrial Earth, 'land' is better understood as something that emerges as a byproduct of these forms of expertise (Li, 2014). In other words, land is what happens when soil is interpreted as use or value.

The implications of this for landscape planning are important and often misunderstood. There has been a tendency to believe that the way soil is valued has nothing to do with how soil is understood as an empirical object. Values, in this model, float above the fundamental science of what soil is and how it works, as if each mode of valuing soil simply represents a deliberately partial view of what is actually well-defined in an entity that is independent and autonomous of those values. In practice, this assumption leads to a great deal of confusion about how soil knowledge could be incorporated into the social and political process of planning.

When soil is understood as property, infrastructure, agricultural resource, or ecosystem service, it has been interpreted through the lens of a specific value. What is crucial to understand, however, particularly for people doing interdisciplinary work like planning, is that different ways of valuing the soil have produced different epistemologies for knowing the soil. Over time, the tendency to continually improve the methodology through which such a value is detected in the soil produces its own tools, techniques, terminology, and protocols. For example, the value of soil stability for foundations leads to the application of concepts

*Princeton-Mellon Fellow in Architecture, Urbanism, and the Humanities.

such as 'strain rate,' as well as the invention of tools and protocols to measure it in different soils, and then eventually to the building regulations that become codified as civil law protections for local and national governments.

Over the course of the 20th century, the fundamental importance of soil for all aspects of political and economic life has resulted in a radiation (to use the evolutionary term) of soil-related disciplines, each with their own expertise in detecting different values in the soil. Crucially for the planner, not all of this knowledge is mutually compatible. For example, the soil that geotechnical engineers describe deep under a building is, for agronomists, not soil at all. In this case, what is meant by the word 'soil,' differs considerably, as do the tools and techniques used to describe it. While these differences are clear to the researchers and practitioners in each respective soil-related discipline, planners are tasked with overlapping many different forms of expertise, often quite literally. In what follows, I will outline a brief conceptual history of how soil knowledge has been 'overlapped' with other forms of knowledge in 20th century planning procedures. This history will serve as an introduction to understanding the challenges soil poses to conventional planning paradigms, and how knowledge about the soil might be utilized more effectively in planning processes in the future.

Turning the soil layer on: Two challenges for soil mapping

Historically, the way in which knowledge about soil has been incorporated into planning models is through a very particular technology, which began as the map overlay. The map overlay has been the 20th century engine of landscape planning and its related disciplines, particularly as it developed as the conceptual basis of geographic information systems (GIS). In these models soil typically appears, unsurprisingly, as a layer in order to be overlapped with other kinds of geospatial information (Fig. 1).¹ The soil layer in landscape planning maps has long provided crucial insights about geotechnical stability, agricultural potential, landslide risk, forest quality, recreational value, septic suitability, and flood risk. The ability to compare land use against soil properties has appeared early and often in the decision-making trees used by landscape planners (Marsh, 2010).

However, soil is not easily reduced to a map layer, even when planning goals are very narrowly defined (Gordon and Gordon, 1981). The inherent three-dimensionality of soil profiles and their catenas across diverse landscapes and climate regimes has challenged soil scientists since the earliest days of the profession. It is also important to understand that these early days were not very long ago. The concept of soil as something that consists of layers that grow and are distinct from rock dates only to the 1880s. The challenge since this recent beginning has been to see patterns within the astonishing diversity of soils around the world and, crucially, to name these patterns. However, this problem of how to name the soil (also known as soil taxonomy) has historically been inseparable from the problem of how to map the soil. The World Reference Base (WRB) soil taxonomy is a good example of this close relationship between mapping and naming, as it began as the map legend to the FAO–UNESCO World Soil Map (Nachtergaele, 2003). This United Nations funded mapping project was the first and most important attempt to make soil knowledge available to planners, and its ambitions were vast (Selcer, 2018). The World Soil Map was intended to provide a definitive catalog of the world's soil resources, making it possible to plan soil on a global scale. However, to accomplish this goal, vastly different kinds of soil knowledge had to be reconciled. René (Rudy) Dudal, who was the lead author of the *World Soil Map*, describes different systems of soil classification as not just describing things differently, but as describing 'different realities.'

This work was undertaken primarily in an attempt to overcome the lack of correlation that has hitherto characterized the field of soil cartography, in which various countries had established their own nomenclatures, survey methods and systems of classification. In particular, those who favoured a genetic classification of soils found themselves in opposition to those who advocated a classification based on morphological criteria. This made any comparison or exchange of information extremely difficult. The point had been reached at which the nomenclatures used could not be translated because terms which at first glance appeared to have equivalents in other languages did not, in fact, cover the same realities; this entailed a very great risk of misunderstanding and practical error (Dudal and Batisse, 1978).

For Dudal and his team, what was untranslatable between systems of soil classification around the world was not language but values. Just as geotechnical engineers and agronomists classify soil in ways that are not only different but mutually exclusive (as we saw above), so too do rice farmers in the Mekong Delta and tax-collectors in Central Mexico. For global systems of soil taxonomy to emerge at all, a consensus had to emerge among diverse forms of expertise for which soil properties to privilege in the naming (and mapping) of soil. In this sense, what Dudal is describing above is not just the rectification of maps at different scales and projections, but the rectification of the values that would determine the tools, techniques, and protocols of soil naming at a global scale.

This kind of scientific consensus is still an ongoing project, but a key benefit of this procedure has already become apparent. Establishing a common language for communicating soil knowledge has made it possible to share knowledge between regions with similar soil conditions that are separated by large geographic distances. It has also facilitated a greater integration between botanical and pedological research, revealing new ecological relationships and agricultural opportunities. While such a consensus is also particularly helpful for interdisciplinary work like planning, the system has its hazards. In data collection terms, soils are not like topography, where the distance between data collection and mapping is very small or fully automated. The labor of interpretation that takes place between observing soil properties and mapping them is still significant and often costly. This labor of interpretation

¹Fig. 1 is an ideogram originally developed as a nationally distributed poster for a 1984 seminar led by Bernard J Niemann, Jr., entitled "Seminar on the Multipurpose Cadastre: Modernizing Land Information Systems in North America." The figure was also republished in Tulloch DL (1999) Theoretical Model of Multipurpose Land Information Systems Development. *Transactions in GIS* 3, (3): 259–283.

Fig. 1 The traditional map overlay method for landscape planning.

takes diverse forms around the world, and the assumption that this process results in an equivalent and continuous data set over large geographical areas has made soil mapping a deeply political exercise (Selcer, 2018).

The widespread assertion that so-called “tropical soils” have poor soil fertility turned out to be an error based in part on Eurocentric assumptions about plant nutrient cycling (Richter and Babbar, 1991). This Eurocentric bias within the structure of Western soil taxonomic systems created, and continues to create, poor policy decisions in tropical and subtropical regions where soils have formed at the intersection of vastly different socio-ecological contexts. For example, undervaluing soil fertility in the Colombian Amazon resulted in the exclusion of small agro-ecological producers from state support and financial credit, exacerbating their struggle to find alternatives to cocoa production amid the US–Colombia policy of anti-drug aerial fumigation (Lyons, 2020).

Arid landscapes have also been subject to similar errors in the evaluation of soil quality. A wide variety of landscapes outside temperate rainfall norms have been mislabeled as deserts, which in the temperate imagination serves as a synonym for low-value land. In some contexts it has also served as a metonym for soil degradation, particularly when their environmental histories have been written by European colonizers (Davis, 2007, 2016). This kind of ‘climate’ in the colonial imagination is still active and commonplace today. For example, in 1946 a doctor named Richmond Anderson decided to study the diet of indigenous Hñähñu people living in the Central Mexican Plateau for the United States Public Health Service in order to document what he believed would be a case of severe malnutrition (Anderson et al., 1946). This region of Mexico receives less than 500 mm of rain per year and has historically been considered infertile and of no agricultural value. Instead of malnutrition, Anderson found a population eating a mainly vegetarian diet of xerophytic plants with no nutritional deficit whatsoever. Many of these plants relied on crassulacean acid metabolism (CAM) photosynthesis, and produced a healthy diet from soil that could never sustain the kinds of foods recommended by global public health standards, such as wheat (*Triticum aestivum* L.), rice (*Oryza sativa* L.), or dairy products.

In this sense, the concept of soil fertility contains within it hidden landscapes, climates, and botanical values that are not neutral, and culturally specific. It would be a mistake, however, to think that these different interpretations of soil fertility are simply the result of different opinions about how to interpret the same soil data. For instance, one might imagine that soil fertility is simply a

subjective concept applied to objective soil data. The problem with this interpretation is that in each of the above cases, human beings were actively intervening in the soil in order to give it new qualities, which in an objective sense, were not already there. Understanding how to use the litter layer to farm under fumigated Amazonian canopy, or how to maintain soil moisture with CAM plants and nitrogen fixing legumes in arid environments like the Central Mexican Plateau resulted in soils with objectively different properties.

This socio-ecological dimension of soil as an empirical object is precisely what makes it so difficult to isolate as the kind of map layer we see in Fig. 1, and so far there have been two primary problems. To recapitulate, the first problem was that the socio-ecological relations between soil and human societies resulted in different kinds of soil knowledge, and therefore different soil taxonomies, which were mutually incompatible at a global scale. In other words, different ideas about how to use soil resulted in different systems for describing it, and therefore different ways of drawing the soil layer on a map. The second problem was that even once a consensus had been established for how to describe and classify soil at a global scale, socio-ecological processes intervened in the process of soil formation at a regional scale in ways that undermined the utility of the classification for planning purposes. The result is that the World Soil Map, like soil taxonomy itself, looks increasingly like an unfinishable project, as it emerges from ongoing practices that shift how the soil is interpreted as value.

For planners, the best place to observe this dual problem of soil mapping is in urban areas, where both of these problems contribute to an almost complete absence of data (See Fig. 2).² On maps of urban areas, soils are typically given generic labels like 'urban land' or 'fill,' which signify the absence of a taxonomic category more than the presence of a well-described soil. Whereas surrounding areas may have detailed information about the soil's horizon structure, pH, texture, and minerals, urban soil often appears homogenous on soil surveys despite its immense material complexity. Like the arid or Amazonian soils above, human intervention has transformed the objective properties of urban soil as an empirical object. Urban processes have effectively intervened in the soil's formation, changing its porosity, chemistry, biology, and capacity for gas exchange, making it indecipherable to the dichotomous keys of, for example, 'Soil Taxonomy,' which is the United States system of classification shown in Fig. 2. For natural historical reasons, the empirical practices that shaped the world's most comprehensive soil taxonomic systems in the 20th century were simply not developed to understand soils formed through processes of urbanization. This has resulted in poor descriptions of the urban soil environment, and an ever widening gap in the soil survey as urban areas expand around the globe.

Today, there is an active and vigorous scientific culture growing around the project of developing new empirical practices capable of interpreting urban soil. Many new initiatives exist to expand traditional soil taxonomic categories to include anthropogenic soils. Soils of Urban, Industrial, Traffic, Military, and Mining Areas (SUITMA) is an active working group of the International Union of Soil Sciences (IUSS), and its members have produced a surge of new research over the last decade. Since 2006, the World Reference Base (WRB) soil taxonomy incorporates high level categories for anthropogenic soils. This is critical research, not only for landscape planning, but for urban environmental health and justice broadly defined. The capacity of soil to filter urban toxicity, mitigate flooding, and support healthy environments is essential for planning urban environments.

Fig. 2 'Urban land' and other classifications from the Soil Survey of the District of Columbia, Washington DC.

²Figure from Smith H (1976) *Soil Survey of District of Columbia*. Washington DC: US Department of Agriculture Soil Conservation Service (USDA).

The socio-ecological dimension of urban soil, however, continues to pose problems for a taxonomic project whose boundaries were circumscribed by the distinction between human and natural history. As such, there has been a tendency to treat anthropogenic soils as if they are simply the same natural materials as before, but simply re-organized into new kinds of shapes and mixtures. In this paradigm, soil science proceeds by analogy. Construction debris is interpreted as if it were a coarse layer of calcareous rock, and the long-term pedological effects of these new calcareous rock layers in the landscape are analyzed according to the chemistry of calcium. This approach has value, but something very specific is lost in the transformation. The process of recognizing only the chemical and physical properties of human history that are legible to existing natural historical frameworks of soil knowledge has a severe side effect, which is that it acts as an efficient filter, removing politics from the soil's history. To remove politics from a soil's history is to limit its utility for planning. For the planner it would be important, for example, to know that the construction debris came from urban renewal. Unlike the quartz or greywacke that a pedologist might identify in a soil profile, construction debris is produced through social relationships, and these relationships matter. If planners do not understand where urban soil comes from, both historically and materially, it becomes difficult to connect policy decisions to their pedological consequences and therefore to make different decisions about what kinds of soil properties to cultivate in the future. Rather than seeing the task of planning in this context as merely assessing the resource value of soil, it is important to recognize that in an urban context, planning produces soil by shaping the conditions of its future formation. The future toxicity, fertility, porosity, or stability of urban soils, among other properties, will depend on decisions that are made today.

Making decisions: The politics of cause and effect in socio-ecological systems

From this perspective, it should start to become clear why visualizing soil as an independent layer that one could overlay with other land-use layers on a planning map is problematic. In a naïve way, one might ask if soils determine the land-use layer, or if land use determines the soil layer? The division between these layers formalizes an assumption about the natural historical quality of soil that events in the 20th century have called into question or, at the very least, made inconvenient. Today, these layers are increasingly inextricable.

Fundamentally, thinking about the relationship between the soil and land use layers of a planning map is about connecting soil to its consequences. What are the consequences of soil and soil formation for 'land,' as a category of use and value? As we have seen, this question is not easy to answer empirically. The empirical process of analyzing soil already contains certain values that are not always independent of land use, but there is also another difficulty here. Even when soil processes are considered entirely 'natural,' isolating cause and effect relationships can be difficult, and this is a problem that soil scientists have struggled with for generations. The great soil scientist Hans Jenny tells a story about the difficulty of narrating cause and effect in the Mendocino pygmy forest, in California (Jenny et al., 1969). According to Jenny, botanists would bring their students to Mendocino and explain how the pygmy forest was the result of a very acidic soil, whereas soil scientists would bring their students to the same spot and explain, to the contrary, that it was the acidic leaves of the forest's ericaceous plants that produced the acidic soil. In this system plants and soils were co-producing one another, and for Jenny, this was a story about the need to think dialectically about the distinction between biology and geology in ecosystems in general. However, Jenny could just as easily have been speaking about the relationship between people and soil in a city or on a farm. There is a reciprocal relationship between soils and land use that is bi-directional and time-dependent. Causality in these systems is often more circular than linear. While this kind of holistic environmental thinking may produce less reductive descriptions of purely ecological systems, they tend to present a political problem for planners and politicians, however, whose policy decisions are measured by how clearly they appear to be the origin of change.

The first systematic attempt to think about this problem in relation to soil was Piers Blaikie's, 1985 book *The Political Economy of Soil Erosion in Developing Countries* (Blaikie, 1985). Here, Blaikie's central question was why policy initiatives to reduce soil erosion were so often unsuccessful, or even worsened the problems they intended to solve. His conclusion was that soil erosion tends to be perceived by development organizations as a purely technical problem to be remedied with terracing, agricultural equipment, crop rotation, population control, or the technical education of a misinformed peasantry. The inability of international development agencies and non-governmental agencies (NGOs) to solve soil erosion problems was a result of the narrowness of this technical approach, which according to Blaikie was narrow by design, given the need to demonstrate policy effectiveness through quantitative cause and effect benchmarks that could be reported to funders. Blaikie called this the "colonial approach to erosion and conservation," and argued that soil degradation was actually a distant and downstream byproduct of the interaction between soil and social relations, many of which were determined by global economic forces and local historic inequalities in land tenure, taxation, and political agency (Blaikie, 1985, p. 53). In Blaikie's research, there was no easy linear causal mechanism available to address soil erosion, only complex bi-directional models of socio-ecological change. Consider, for example, the difference between the typical layer-based model of soil shown in Fig. 1 and Blaikie's model in Fig. 3. Here, soil is not represented as a layer that can be overlapped with other social and ecological data. Instead, the soil map-layer appears as a dynamic form within the socio-ecological processes that shape it. In this model, the linear boundaries of the soil shown on the map reflect social relations as much as soil formation. In Fig. 3 one might say that the layer-cake model (Fig. 1) has collapsed under its own weight like a soufflé.

Blaikie (1985) focused only on soil erosion, but his findings are still relevant to the way we think about the socio-ecology of soil. For example, today's United Nations Sustainability Goals (SDG 12) call for reductions in carbon dioxide (CO₂) emissions in modern agricultural practices. While CO₂ emissions provide a quantifiable benchmark for progress on this goal, it is only achievable through significant social and political change. Chefs and seed savers may turn out to be as important to this transition as farmers,

Land use decisions and soil erosion

politicians and regulatory bodies, particularly as climate change affects the seasonality and water efficiency of food. Setting goals for what kinds of soils to cultivate requires an intervention in fundamental aspects of both gastronomy and economy, and from this perspective soil science looks increasingly like a planning discipline.

After the collapse of the layer cake model: Rethinking the relationship between soil and land-use

In Southern China, the discovery of soil-dependent strains of cadmium-excluding rice has made the interconnection between soil and planning particularly clear. In the southern provinces of Hunan, Guizhou, Jiangsu and Guangdong, mining and industrial corridors have left a legacy of cadmium-contaminated soils in close proximity to rice production. According to a national survey by China's Ministry for Land and Resources in 2014, almost 20% of China's arable land is now contaminated (Zhao et al., 2015). The cadmium that the rice plant absorbs from these soils is transferred to the grain, contaminating the food supply and causing "Itai-itai" disease, which translates as "it hurts-it hurts" disease, in reference to the severe spine and joint pain that cadmium poisoning causes. Rice is currently a staple crop for 3 billion people, which means that the vast legacy of post-industrial toxicity in Asia cannot easily be fixed by simply abandoning rice production in these areas. Even if this was an option, the precise boundaries of the contamination are not known. To survey agricultural soils for contamination in China required an astonishing 787,500 soil samples to cover an area of 6.3 million square kilometers. At this scale, each sample represented an area of 8 km². Moreover, the most dangerous soils in this context are the ones that are only slightly contaminated, where cadmium levels are not high enough to kill the plants but still high enough to accumulate in the rice grain. How many more samples would be needed to delineate clearly the subtle edge of this boundary for China as a whole?

Over the last several decades researchers have been trying to address this problem through a soil-dependent pathway that takes advantage of the biology of the rice plant. As a wetland species adapted to aquatic environments, the aerenchyma of the rice plant transports oxygen to the roots for respiration. Roughly 30–40% of this oxygen is lost to the environment through root pores and wherever it comes into contact with iron in the soil a metallic 'plaque' forms on the roots (Cheng et al., 2014). This rusty plaque is an effective filter against cadmium uptake, and the result is that specific strains of oxygen exuding rice in combination with iron rich soil have the potential to dramatically improve food safety in China (Chen et al., 2017; Rahimi et al., 2021).

If there was a 21st century post-industrial version of Hans Jenny's parable in the Mendocino coastal terraces, this might be it. A plant–soil interaction has re-drawn land-use boundaries in China through selective plant breeding, activism, land-use change, and public health research. No one element in the process could be called the origin of this new socio-ecological compromise. It is important to note however, that the cadmium is still in the soil and will stay there for the foreseeable future. Nothing has been cleaned up, and in this sense there is little to celebrate. However, in the 21st century, toxicity is not a binary condition of 'present' or 'absent' but rather a pervasive condition that has disproportionate effects on low income and people of color in both wealthy and developing nations. Instead of avoiding toxicity, which requires resources and is typically a privilege reserved for the environmental enclaves of the wealthy, it will be increasingly important to develop transparent and public strategies for surviving this condition. For the chemistry and biology of toxicity to be included in political forums there needs to be public trust in the way toxicity is represented, or made visible. For trust to be established, these discussions should not only occur in the context of a public health crisis. Transparent environmental monitoring and reporting of health risks needs to become a public utility, like electricity or water, to provide the time and space necessary to address environmental problems with long-term planning rather than short-term crisis measures. Soil is arguably the most critical buffer against environmental toxicity. Conserving the soil properties that support this function will increasingly require this kind of integrated approach to understand the geo-biology of land-use change.

Soil futures: A new discipline

Given the centrality of soil to global sustainability goals, what should the future of soil science and landscape planning look like? What would it mean to cultivate an expertise in this area adequate to the challenges we are now facing in an uncertain climate?

Today, the vast majority of published information on the relationship between soil and land use falls into one of two categories: resource extraction or damage control. In the resource extraction paradigm, the properties of soil are assessed for how well they might support or prohibit a particular land use. In the damage control paradigm, a particular land use has caused some degree of soil degradation and the question is what to do about it, or how things might have been done differently. In these paradigms, soil is either a pristine natural resource to be utilized or the material aftermath of some lamentable event. What these well-known genre's of applied soil research have in common is the basic conceptual division enacted by the layer-based model of soil in the human environment: in the first paradigm soil is a cause and land use is the effect, whereas in the second the order is reversed: land-use causes soil degradation. In order to think about soil and landscape planning in the 21st century, a new genre of soil narrative will need to be invented. Rather than assessing resource stocks or documenting degradation, one question we could ask is the following: how could a future soil be planned through the soil forming effects of land-use relationships? Could these relationships be environmentally just, decolonial, and climate aware? What kinds of circular economies might cultivate soil resources rather than degrade them? Designing land-use strategies around their soil forming effects would constitute the methodology for a discipline that does not yet exist. However, the political and environmental conditions which produce the need for such a discipline are already clear. If soil and landscape planning remain as distinct as the title of this entry suggests, then perhaps we need a new discipline to address these challenges. What would a degree in 'soil futures' look like?

EDITORS BIOGRAPHY

Michael J Goss, PhD, MSc, BSc, is a professor emeritus in the School of Environmental Sciences at the University of Guelph. Before taking on the joint editor-in-chief responsibilities with Margaret Oliver, he held a similar position for *Soil Use and Management*, a journal of the British Society of Soil Science of which he is an honorary fellow. He was an inaugural member of the European Society for Agronomy. Michael started his career at the Letcombe Laboratory before moving to Rothamsted Experimental Station and the Macaulay Land Use Research Institute (now the James Hutton Research Institute). In 1990 he was appointed to the Research Chair in Land Stewardship at the University of Guelph and in 2005 became the director of its Regional Campus near Ottawa.

Michael's research has covered soil plant relations, soil management, and agriculture's footprint on the environment. His focus has been on the physical properties of soil and their impacts on root growth, which he showed to be influenced by the role of the root cap. He broadened his approach to include the effects of tillage and land drainage on root exploration. This work stimulated his interest in the transport of materials, such as plant nutrients, pathogenic microbes, antibiotics, and biologically active compounds through the soil and their contamination of water resources. Michael's knowledge in this field resulted in his involvement in the public inquiry into the death of seven people, including children, from a microbially contaminated drinking water supply. He contributed, both to the investigation into how the contamination occurred and if any fault could be attributed to local agricultural practices, and to how to prevent future events.

Michael also developed an interest in the interrelationships between soil microbes and root systems, particularly the tripartite symbiosis between roots of legumes, mycorrhizal fungi, and rhizobia. He has been an energetic member of collaborative research programs in France and Germany, and in Portugal, where he continues his interest in the role of mycorrhiza in sustainable land management.

Michael has authored more than 180 publications including two books, one in its 2nd edition, and edited two others.

Margaret Ann Oliver (BSc, PhD)

Margaret's interest in soil began in her penultimate year at school when learning about different types of soil and their formation. She chose the University of Bristol, United Kingdom for her first degree because the geography course offered soil science and she was also able to do a degree in geology alongside. Her love for both subjects remains undiminished. She did her PhD in soil spatial analysis at the University of Birmingham. Her early research focused on the multivariate and geostatistical analysis of soil data, which she continued to use in various research projects. Her research interests expanded to include the application of a wide range of numerical and geostatistical methods to soil and other data including pollen counts, forestry, radon emission, remotely sensed imagery, precision agriculture, and the incidence of childhood cancer. Her specific interests have been in sample design for spatial analysis and eventual mapping, risk analysis associated with prescribed thresholds in relation to soil pollutants or deficiencies of crop nutrients, and the relations between different scales of spatial variation. Her most

recent research was in the field of precision agriculture. At both the Universities of Birmingham and Reading, she taught topics in soil science, statistical methods, and spatial analysis. At Reading she had a research group working on various projects such as imagery, sampling and mapping, precision agriculture, and human health.

She has published more than 100 academic papers and has made several contributions to books. She is the co-author of three books: *Statistical Methods in Soil and Land Resource Survey*, Oxford University Press (Webster, R and Oliver, M. A. 1990); *Geostatistics for Environmental Scientists*, Second Edition, John Wiley & Sons (Webster, R and Oliver, M. A. 2007), and *How to do the Basic Steps in Geostatistics: The Variogram and Kriging*, Springer, Dordrecht (Oliver, M.A. & Webster, R.2015). She has edited two books: *Geostatistical Applications for Precision Agriculture* (Springer, Dordrecht, 2010) and *Precision Agriculture for Sustainability and Environmental Protection* (Earthscan from Routledge, 2013).

Margaret retired officially from Reading in 2004, but as yet has not managed to escape from academia. She has retained a link and a base at the University as a visiting professor since January 2005. After retirement, she developed and taught geostatistics courses to outside groups for several years. She then started on the long path of editorial work, as an associate editor of the *European Journal of Soil Science* and eventually the editor-in-chief, assistant editor of *Mathematical Geosciences*, co-editor of *Precision Agriculture* with John Stafford, and finally the editor-in-chief of the *Encyclopedia of Soils in the Environment* with Michael Goss.

Margaret was made an honorary member of the British Society of Soil Science in 2021 to reflect her commitment to soil science through fellow research, teaching, and editorial work. She was honored by the Pedometrics Commission of the International Union of Soil Science by having an award named after her in 2015. It is the Margaret Oliver award for young pedometricians.

EDITORIAL BOARD

Editors in Chief

FOREWORD

Soil is the porous “skin” on the surface of the Earth that has formed over thousands of years of weathering, comprising minerals, organisms (both dead and alive), water, and air. Soil is more than just the sum of its parts. It serves several crucial ecological functions, from food and fiber production to water storage and purification to waste decomposition.

Increasingly we understand that everything is connected, and that soil is a “Critical Zone” that intersects with the hydrosphere (water), lithosphere (minerals), atmosphere (air), and biosphere (all living organisms). To quote Daniel Hillel, the 2012 World Food Prize laureate and editor of the First Edition of *The Encyclopedia of Soils in the Environment*, “[Soil] is the crucible of terrestrial life, within which biological productivity is generated and sustained...Our civilization depends on the soil...” He also promoted the importance of understanding soil to manage it effectively. This revised and reorganized second edition of the Encyclopedia aims to reflect the changing status of soil in the world. Within these five volumes, over 724 experts from many countries have provided updated, easy-to-understand chapters on soil, its properties, and its role in the environment to affect climate change, plant productivity, human health, and biodiversity.

Many technological advances have been made since the first edition of this encyclopedia that has allowed us to investigate soil physical, chemical, and especially biological properties more precisely, enabling us to identify and understand their roles in ecosystem services. The study of soils, especially in the environmental context, is critical to meeting the challenges of feeding, clothing, and cleaning up the world. The information presented in these volumes will be useful to many, including soil and environmental scientists, policymakers, land managers, educators, students, and anyone interested in learning more about soil.

Soil is under considerable threat from many sources—building and infrastructure, climate change, population pressure, and pollution, yet it is vital to agronomic productivity and continues to provide critical ecosystem services. Society needs to be engaged in how soil is managed and conserved. Most natural scientists are very dedicated and generous, including all of the authors in this Encyclopedia who have freely given their time to make these volumes so comprehensive. The study of soil, while often challenging, is fascinating—soil is a beautiful earthy material that can delight our senses with its variegated colors, gritty to smooth textures, and especially its characteristic aroma when freshly turned. Perhaps that is why gardeners and even some farmers tend to overwork their soil to its detriment—it *just feels good to get your hands in the dirt!*

Soil science is one of the most exciting, interesting, and rewarding disciplines, largely because it is multi-dimensional and interdisciplinary, basic and applied. It affects all of our lives. Thus, I encourage you to peruse these volumes and discover all kinds of interesting aspects of soil in the environment.

April Ulery

Former President, Soil Science Society of America
Professor, Soil & Environmental Sciences
New Mexico State University
Las Cruces, NM
The United States

PREFACE

This second edition of the *Encyclopedia of Soils in the Environment* follows in the footsteps of a highly rated first edition overseen by Professor Daniel Hillel as editor in chief, ably assisted by six editors. That edition provided a very valuable resource on the “state-of-the-art” in soil science in the context of the environment in the closing years of the twentieth century and the first three years of the current century. It set a standard that the editorial team for the second edition has aimed to match. The soil and environmental sciences have made huge strides in the almost 20 years since the first edition was published, and the new team has had to embrace these developments while retaining the basic components of these sciences. The project has taken 4 years to complete. It began with the appointment of the two editors-in-chief, professors Michael J. Goss and Margaret A. Oliver, followed by that of the nine subject editors and a pedology adviser.

The project was in its infancy (a few months only) when COVID-19 struck. The editors-in-chief discussed the format and structure of the second edition around the time that the first “lockdowns” around the world were being introduced. The first edition was alphabetically organized, whereas we decided to have a section-oriented approach in this edition, which we hope gives a more structured feel for the various topics embraced. The principal sections are soil biology, soil chemistry, the soil environment and its management, pedology (the origins and development of soil), pedometrics (the application of mathematics and statistics to soil), and soil physics. We were able to give our full attention to this development and to the selection of the scientists to join us on the road ahead. Furthermore, we were fortunate to choose a team that has maintained its enthusiasm despite the many tribulations we have faced along this path. The team comprises Jane Blagodatskaya and Adrian Unc (biology and microbiology), Siobhan Staunton and Baoshan Xing (chemistry), Karin Müller and Christina Siebe (environment and management), Rupert Bäumler (pedology), Uta Stockmann and Margaret Oliver (pedometrics), and Paul Hallett and Dani Or (physics). The editorial board has been mindful in their choice of subjects of the need for basic soil science and for state-of-the-art developments, with the aim that the audience for these volumes can be as large as possible.

During the gestation period of the Encyclopedia, methods of working for those in academia were turned on their heads. The change from “face-to-face” teaching to formulating and establishing online courses, initially for lockdown periods but then for much of the next 2 years, had huge consequences for academic staff worldwide. This meant that they had less time to devote to outside activities, such as writing chapters for an encyclopedia. As a result, some authors were unable to complete their chapters in time, leaving a few unfortunate gaps. The whole team has done as much as they can to limit any adverse effects, but we ask readers to appreciate the struggle that authors have had with illness (personal, within their families and work colleagues) and a great increase in their workload. Despite this, we are presenting a comprehensive document that should stand the test of the next 20 years of soils in the environment.

This century has seen an almost unprecedented interest in the soil and environmental sciences. It has been triggered not only by issues that the Earth is facing from global climate change, increasing population pressure, soil and land degradation, and food insecurity but also by the many new and sophisticated methods available, such as the DNA determination of microbial populations and their functional capabilities, proximal sensing, machine learning methods, and an ever-increasing array of technological tools. These developments have greatly increased our knowledge and appreciation of the complexity of soils, which has changed our understanding of some well-established aspects of the science. The soil and its environment are at the critical interface of the atmosphere, biosphere, hydrosphere, and lithosphere. They deserve to be taken seriously by the international community in the same way that air and water have been. Governments are now paying attention

to the soil and environment, and a legal and governance framework is emerging to look after these parts of our life support resources.

We have aimed, through our editing of chapters, to make the language of the chapters accessible to all, regardless of educational background. This does not mean that we have diminished the scientific content, but that readers should be able to gain the foothold they desire in these subjects to progress to greater knowledge and understanding of them. We have retained the overview of soil written by Daniel Hillel for the First Edition, first to honor his great contribution to soil science and second to demonstrate the significance of soil. It follows this Preface.

*Michael J. Goss
Margaret A. Oliver*

SOIL

The term “soil” refers to the weathered and fragmented outer layer of our planet’s land surfaces. Formed initially through the physical disintegration and chemical alteration of rocks and minerals by physical and biogeochemical processes, soil is influenced by the activity and accumulated residues of a myriad of diverse forms of life. As it occurs in different geologic and climatic domains, soil is an exceedingly varied body with a wide range of attributes.

Considering the height of the atmosphere, the thickness of the earth’s rock mantle, and the depth of the ocean, one observes that soil is an amazingly thin body—typically not much more than one meter thick and often less than that. Yet it is the fount of terrestrial life, within which biological productivity is generated and sustained. It acts like a composite living entity, a home to a community of innumerable microscopic and macroscopic plants and animals. A mere fistful of soil typically contains billions of microorganisms, which perform vital interactive biochemical functions. Another intrinsic attribute of the soil is its sponge-like porosity and its enormous internal surface area. That same fistful of soil may actually consist of several hectares of active surface, upon which physicochemical processes take place continuously.

Realizing humanity’s utter dependence on the soil, ancient peoples, who lived in greater closeness to nature than many of us today, actually revered the soil. It was not only their source of livelihood but also the material from which they built their homes and that they learned to shape, heat, and fuse into household vessels and writing tablets (ceramics, made of clayey soil, being the first synthetic material in the history of technology). In the Bible, the name assigned to the first human was Adam, derived from “adama,” meaning soil. The name given to the first earthling’s mate was Hava (Eve, in transliteration), meaning “living” or “life-giving.” Together, therefore, Adam and Eve signified quite literally “Soil and Life.”

The same powerful metaphor is echoed in the Latin name for human species—Homo, derived from humus, the material of the soil. Hence, the adjective “human” also implies “of the soil.” Other ancient cultures evoked equally powerful associations. To the Greeks, the earth was a manifestation of Gaea, the maternal goddess who, impregnated by Uranus (god of the sky), gave birth to all the gods of the Greek pantheon.

Our civilization depends on the soil more crucially than ever because our numbers have grown while available soil resources have diminished and deteriorated. Paradoxically, however, even as our dependence on the soil has increased, most of us have become physically and emotionally detached from it. Many of the people in the so-called developed countries spend their lives in the artificial environment of a city, insulated from direct exposure to nature, and some children may now assume as a matter of course that food originates in supermarkets.

Detachment has bred ignorance, and out of ignorance has come the delusion that our civilization has risen above nature and has set itself free of its constraints. Agriculture and food security, erosion and salination, degradation of natural ecosystems, depletion and pollution of surface waters and aquifers, and decimation of biodiversity—all these processes, which involve the soil directly or indirectly, have become abstractions to many people. The very language we use betrays disdain for that common material underfoot, often referred to as “dirt.” Some fastidious parents prohibit their children from playing in the mud and hurry to wash their “soiled” hands when the children nonetheless obey an innate instinct to do so. Thus, soil is devalued and treated as unclean though it is the terrestrial realm’s principal medium of purification, wherein wastes are decomposed and nature’s productivity is continually rejuvenated.

Scientists who observe soil closely see it in effect as a seething foundry in which matter and energy are in constant flux. Radiant energy from the sun streams onto the field and cascades through the soil and the plants growing in it. Heat is exchanged, water percolates through the soil’s intricate passages, and plant roots extract

water and transmit it to their leaves, which transpire it back to the atmosphere. Leaves absorb carbon dioxide from the air and synthesize it with soil-derived water to form the primary compounds of life. Oxygen emitted by the leaves makes the air breathable for animals, which consume and in turn fertilize plants.

Soil is thus a self-regulating bio-physio-chemical factory, processing its own materials, water, and solar energy. It also determines the fate of rainfall and snowfall reaching the ground surface—whether the water thus received will flow over the land as runoff, or seep downward to the subterranean reservoir called groundwater, which in turn maintains the steady flow of springs and streams. With its finite capacity to absorb and store moisture, and to release it gradually, the soil regulates all these phenomena. Without the soil as a buffer, rain falling over the continents would run off entirely, producing violent floods rather than sustained river flow.

Soil naturally acts as a living filter, in which pathogens and toxins that might otherwise accumulate to foul the terrestrial environment are rendered harmless. Since time immemorial, humans and other animals have been dying of all manner of diseases and have then been buried in the soil, yet no major human disease is transmitted by it. The term antibiotic was coined by soil microbiologists who, as a consequence of their studies of soil bacteria, specifically actinomycetes, discovered streptomycin (an important cure for tuberculosis and other infections). Ion exchange, a useful process of water purification, also was discovered by soil scientists studying the passage of solutes through beds of clay.

However unique in form and function, soil is not an isolated body. It is, rather, a central link in the larger chain of interconnected domains and processes comprising the terrestrial environment. The soil interacts both with the overlying atmosphere and the underlying strata, as well as with surface and underground bodies of water. Especially important is the interrelation between the soil and climate. In addition to its function of regulating the cycle of water, it also regulates energy exchange and surface temperature.

When land is cleared of vegetation and turned into a cultivated field, the native biomass above the ground is often burned and the organic matter within the soil tends to decompose. These processes release carbon dioxide into the atmosphere, thus contributing to the Earth's greenhouse effect and to global warming. On the other hand, the opposite act of afforestation and soil enrichment with organic matter, such as can be achieved through conservation management, may serve to absorb carbon dioxide from the atmosphere. To an extent, the soil's capacity to store carbon thus helps to mitigate the greenhouse effect.

Thousands of years are required for nature to create life-giving soil out of sterile bedrock. In only a few decades, however, unknowing or uncaring humans can destroy that wondrous work of nature. In various circumstances, mismanaged soils may be subject to erosion (the sediments of which tend to clog streambeds, estuaries, lakes, and coastal waters), to leaching of nutrients with attendant loss of fertility and eutrophication of water bodies, to waterlogging and impaired aeration, or to an excessive accumulation of salts that may cause a once-productive soil to become entirely sterile. Such processes of soil degradation, sometimes called "desertification," already affect large areas of land.

We cannot manage effectively and sustainably that which we do not know and thoroughly understand. That is why the tasks of developing and disseminating sound knowledge of the soil and its complex processes have assumed growing urgency and importance. The global environmental crisis has created a compelling need for a concentrated, concise, and definitive source of information—accessible to students, scientists, practitioners, and the general public—about the soil in all its manifestations in nature and in relation to the life of humans.

Studying soil microbial communities: Culture-independent approaches	146
<i>Tolulope Mafa-Attoye, Heather Slinn, Micaela Tosi, Evan Mayer, Dasiel Obregon, and Kari Dunfield</i>	

Studying microbial function in soil: Culture-independent techniques <i>Micaela Tosi, Dasiel Obregon, Heather Slinn, and Kari Dunfield</i>	155
Kinetics of microbial processes: General principles <i>NS Panikov</i>	168
Kinetics of microbial processes: Applications to soil biology <i>NS Panikov</i>	186
Biogeochemical cycles	
Carbon cycle in soils: Dynamics and management <i>Charles W Rice, Carlos B Pires, and Marcos VM Sarto</i>	219
Carbon storage in soils <i>Isabelle Basile-Doelsch, Tiphaine Chevallier, Marie-France Dignac, and Amandine Erktan</i>	228
Soil organic nitrogen <i>EJ Daly and KA Congreves</i>	243
Nitrification: Process, organisms and management <i>Jeanette M Norton and Yang Ouyang</i>	253
Microbial denitrification <i>Michael J Goss, Sergey Blagodatsky, and Adrian Unc</i>	261
Symbiotic nitrogen fixation <i>Florence Mus and Hsin-Hua Wu</i>	270
Nitrogen: Non-Symbiotic Nitrogen fixation in soils <i>Vadakattu VSR Gupta and Sarah S Roley</i>	283
Phosphorus in soils—Biological interactions <i>Nataliya Bilyera and Iryna Loginova</i>	293
Biological transformations of sulfur in soil <i>Chaoqun Wang and Maxim Dorodnikov</i>	303
Plant uptake of mineral nutrients <i>Angela Hodge</i>	310
Higher plants and their interactions with soil organisms	
Soil Biology: Root form and function <i>Magda Garbowski, Grégoire Freschet, Louise Jackson, Cynthia Brown, and Louise Comas</i>	321
Root mucilage: Chemistry and functions in soil <i>Yutong Jiang, Lijun Hou, Fang Ding, and Joann K Whalen</i>	332
Root exudates and microorganisms <i>Aidan De Sena, Krisztina Mosdossy, Joann K Whalen, and Chandra A Madramootoo</i>	343
Root interactions with the microbiome from the rhizoplane to the bulk soil: An overview <i>Joann K Whalen and Shamim Gul</i>	357
Microorganisms & biological processes	
Soil respiration <i>Jeremiah D Vallotton, Sergey Blagodatsky, and Adrian Unc</i>	369
Anaerobic soil processes <i>PW Inglett, D Said-Pullicino, and K Ramesh Reddy</i>	379
Mineral-organic-microbial interactions <i>Balwant Singh, Sabina Yeasmin, and Donald L Sparks</i>	387

Microbial ecology & management

Habitat for soil organisms and their functions <i>Alexandra Kravchenko and Andrey Guber</i>	407
Plant growth promoters <i>Elisa Gamalero, Gustavo Santoyo, and Bernard R Glick</i>	418
Inoculation with microorganisms <i>Maureen O'Callaghan and David Wright</i>	428
Biocontrol of soil-borne plant diseases <i>Mehrdad Mohammadiani and Matthew Bakker</i>	439
Management of soil biology for crop protection from biotic and abiotic stresses <i>Michael J Goss, Isabel Brito, and Mário Carvalho</i>	447
Trees, hedges, agroforestry and microbial diversity <i>Josiah B Judson, Joseph Holden, Pippa Chapman, and Marcelo Valadares Galdos</i>	469
Urban soil microbiome: Activity, diversity and functioning <i>Maria Korneykova, Ekaterina Kozlova, Kristina Ivashchenko, Maria Vasilieva, and Viacheslav Vasenev</i>	480
Microbiology of extreme soil environments <i>Patrice Dion</i>	494
Microbial mobility and transport in soils <i>Mohammad Reza Mosaddeghi, Adrian Unc, Ali Akbar Mahboubi, and Azadeh Safadoust</i>	512

Biology of soil amendments & contaminant degradation

Biology of compost <i>Heribert Insam, Thomas Klammersteiner, and María Gómez-Brandón</i>	522
Landfarming and its microbiology <i>Naga Raju Maddela, Balasubramanian Ramakrishnan, Kadiyala Venkateswarlu, and Mallavarapu Megharaj</i>	533
Biodegradation of organic contaminants <i>PB Hatzinger and JW Kelsey</i>	547
Biological aspects of manure management <i>Natasha Rayne and Bee Khim Chim</i>	558
Septic systems and municipal waste disposal on land <i>Charles P Gerba, Michael J Goss, and Adrian Unc</i>	567

Climate change

Climate change impacts on soil biology <i>Alberto Canarini, Lucia Fuchslueger, François-Xavier Joly, and Andreas Richter</i>	578
---	-----

VOLUME 2: CHEMISTRY**Basic Soil Chemistry**

Acidity and acidification <i>Siobhan Staunton</i>	1
pH <i>Siobhan Staunton</i>	8
Buffering capacity <i>Siobhan Staunton and Ravi Naidu</i>	15
Soil specific surface area <i>Emmanuel Arthur, Markus Tuller, and Kurt D Pennell</i>	22

Soil Analytical Chemistry

Cation exchange capacity and reactions <i>Donald S Ross and Ulf Skyllberg</i>	32
Testing for nutrients in the soil and the environment <i>Antonio P Mallarino</i>	43
Metal extraction and analysis <i>Guo Wang and Honghong Li</i>	50
Soil organic matter: Composition <i>Markus Kleber</i>	58
Physical fractionation techniques <i>Sam J Leuthold, Michelle L Haddix, Jocelyn Lavallee, and M Francesca Cotrufo</i>	68
The use of stable isotopes in soil science: Low atomic number elements <i>Chiara Pistocchi, Isabelle Bertrand, Kristýna Kantnerová, Astrid Oberson, Federica Tamburini, and Roland A Werner</i>	81
The use of radioactive isotopes to study soil pools and processes <i>Timothy I McLaren</i>	96
The use of stable isotopes in soil science: Metals <i>Cécile Quantin and Damien Guinoiseau</i>	107

Periodic Table

Alkali metals in soils <i>Guy J Levy and Asher Bar-Tal</i>	116
Alkaline earth metals in soil <i>Justin B Richardson</i>	126
Transition metals in soil <i>Siobhan Staunton</i>	135
Nitrogen and ammonia in soils <i>Nicholas T Girkin and Hannah V Cooper</i>	142
Phosphorus in soil <i>Luisella Celi, Maria Martin, and Elisabetta Barberis</i>	152
Aluminum in soils <i>Syuntaro Hiradate</i>	167
Iron in soils <i>Trolard Fabienne and Guilhem Bourrié</i>	176
Sulfur and selenium in soil <i>Dongli Liang, Fei Zhou, and Mingxing Qi</i>	192
Arsenic in soil <i>Md Imran Ullah Sarkar, Afsana Jahan, Md Tofail Hossain, Mohammad Mahmudur Rahman, and Ravi Naidu</i>	201
Non-transition elements: Metals and metalloids in soils <i>Natasha, Sana Khalid, Muhammad Shahid, Faiz Rabbani, and Camille Dumat</i>	214
Lanthanides, actinides and radon <i>Franco Ajmone Marsan and Mery Malandrino</i>	225
Halogens in soils <i>Svensson Teresia, Thiry Yves, Bueno Maïté, and Oelmann Yvonne</i>	234
Transformation of metals and metalloids by microorganisms <i>Susan M Glasauer, Euan P Burford, and Geoffrey Michael Gadd</i>	243
Dynamics of radionuclides <i>Siobhan Staunton</i>	256
Silicon and other non-metal elements from Group 14 <i>Bruno Delvaux and Zimin Li</i>	263

Soil Physical Chemistry

Chemical equilibria	274
<i>Arthur Paul Schwab</i>	
Dissolution and precipitation processes	284
<i>Zhenqing Shi, Shiwen Hu, Rong Li, and Yang Lu</i>	
Reactions, redox potential and kinetics	297
<i>Trolard Fabienne and Guilhem Bourrié</i>	
Sorption of organic chemicals in soil	315
<i>Joseph J Pignatello</i>	
Sorption—Oxyanions	327
<i>CP Schulthess, H Wijnja, W Yang, Anahita Khosravi, and Baoshan Xing</i>	
Sorption—Metals	336
<i>Daniel G Strawn and Donald L Sparks</i>	
Sorption–desorption kinetics	343
<i>Gautier Landrot and Donald L Sparks</i>	
Sorption-desorption hysteresis	355
<i>Wenhao Wu, Hongxia Zhu, and Kun Yang</i>	
Surface charge and zero-charge points	368
<i>J Chorover</i>	
Flocculation and dispersion	376
<i>Guy J Levy and Isaac Shainberg</i>	

Soil Carbon Chemistry

Soil organic matter dynamics	387
<i>Yu Luo and Jianming Xu</i>	
Soil proteins	396
<i>Siobhan Staunton</i>	
Biochar: Properties, mechanisms, and interactions in the soil	406
<i>Balwant Singh, Shamim Mia, and Marta Camps-Arbestain</i>	
Dissolved organic carbon	421
<i>Jason James and Rob Harrison</i>	
Black carbon, pyrogenic carbon	432
<i>Heike Knicker</i>	
Fire effects on soil	448
<i>Stefan H Doerr, Cristina Santín, and Jorge Mataix-Solera</i>	
Interfacial reactions of microorganisms with minerals and organic matter	458
<i>Rota Wagai, Puu-Tai Yang, and Klaus Kaiser</i>	
Pesticide fate in soils	470
<i>Pierre Benoit, Laure Mamy, Carole Bedos, and Enrique Barriuso</i>	
Soil organic matter in molecular simulations	483
<i>Martin H Gerzabek, Daniel Tunega, Edgar Galicia-Andrés, and Chris Oostenbrink</i>	

Soil Physical Analysis

Raman spectroscopy	497
<i>Anupam Das and Huiyuan Guo</i>	
Fourier transform infrared spectroscopic methods of soil analysis	510
<i>Derek Peak</i>	
Electron paramagnetic resonance spectroscopy: Part I Historic Perspectives	519
<i>Giorgio S Senesi and Nicola Senesi</i>	

Electron paramagnetic resonance spectroscopy: Part II the view forward <i>Robert L Cook, Emmanuel Ampiah, Phillip T Sprunger, and Randall W Hall</i>	533
Fluorescence Spectroscopy: Part I Principles <i>Yong Zhang, Shuai Guo, and Chaoxian Wei</i>	544
Fluorescence spectroscopy: Part II practical applications <i>Yong Zhang, Chaoxian Wei, and Shuai Guo</i>	552
Near and mid infrared soil spectroscopy <i>Wartini Ng, Brendan Malone, Budiman Minasny, and Sangho Jeon</i>	567
Electron microscopic methods (TEM, SEM and energy dispersal spectroscopy) <i>Jian Zhao and Xia Liu</i>	575
Application of atomic force microscopy (AFM) on environmental interfaces <i>Saikat Ghosh, Zhang Di, Bo Pan, and Baoshan Xing</i>	589
Applications of nuclear magnetic resonance for the study of soils <i>Daniel H Lysak, Myrna J Simpson, and Andre J Simpson</i>	605
Neutron-gamma analysis of soil elements <i>Aleksandr Kavetskiy, Galina Yakubova, Nikolay Sargsyan, Stephen A Prior, and H Allen Torbert</i>	625
X-Ray Diffraction <i>Chao Wang and Cheng Gu</i>	642
Soil analysis using laser-induced breakdown spectroscopy <i>Débora Marcondes Bastos Pereira Milori, Ladislau Martin-Neto, Hero T Gollany, Diego Victor de Babos, Luis Carlos Leva Borduchi, and Paulino Ribeiro Villas-Boas</i>	654
Calorimetric analysis <i>Xingmin Rong and Qiaoyun Huang</i>	662
Understanding of soil processes at the microscale—Use of NanoSIMS in soil science <i>Carsten W Mueller, Carmen Hoeschen, and Ingrid Koegel-Knabner</i>	670
Nanoparticles in soil <i>Di Lang, Quan Chen, Yang Liu, and Bo Pan</i>	681
Overview	
Soil chemistry and climate change <i>Jianming Xu, Yong Li, and Zhongmin Dai</i>	692
VOLUME 3: ENVIRONMENT AND MANAGEMENT	
Soil functions, potential uses of soil and ecosystem services	
Soil functions, soil potential uses and ecosystem services <i>Karl Stahr</i>	1
Farming systems to conserve land for nature <i>Rattan Lal</i>	12
Geoarchaeology and soils <i>Carlos E Cordova</i>	20
Civilizations and the role of soil, agriculture, and climate change <i>Jeffrey A Homburg, Eric C Brevik, and Jonathan A Sandor</i>	29
Ecosystem services provided by soils in highly anthropized areas (SUITMAs) <i>Jean Louis Morel, Geoffroy Séré, Viatcheslav Vasenev, and Thomas Nehls</i>	37
Structure and function of forested soils <i>Peter Clinton and Jen Owens</i>	56
Agroforestry <i>NV Thevathasan, AM Gordon, and PKR Nair</i>	68

Rangeland management <i>Alexandra Sandhage-Hofmann</i>	88
Effects on soil of grassland management for pasture, hay and silage <i>Carmen Segura, Laura Cardenas, Richard McDowell, Sarah Morgan, and Martin SA Blackwell</i>	102
Dryland farming: Technological and management options for sustainable agriculture and food systems <i>Ch Srinivasarao, G Ranjith Kumar, Ravula Manasa, Kiran Pilli, Samaresh Sahoo, S Rakesh, Sumanta Kundu, K C Nataraj, KV Rao, JVNS Prasad, and S Malleswari</i>	113
The effect of crop rotations on soil <i>Caio Fernandes Zani, Arlete Simões Barneze, Rogério Peres Soratto, and Charles Andrew Francis</i>	125
The contribution of organic farming systems to soil fertility—A systems perspective <i>Bernhard Freyer, Pierre Ellssel, Jürgen K Friedel, and Kurt Möller</i>	135
Soil functions to support natural plant communities and crops: Soil multifunctionality <i>Leidivan Almeida Frazão, Luiz Arnaldo Fernandes, Adriana Marcela Silva Olaya, and Igor Costa de Freitas</i>	146
Methane and nitrous oxide emissions from land <i>Joanna M Cloy and Keith A Smith</i>	153
Soil and land degradation	
Overview chapter on soil degradation <i>K Müller, Margaret A Oliver, and C Siebe</i>	165
Soil monitoring <i>Ben Marchant and Nicolas Saby</i>	172
Soil quality and health key indicators <i>Edoardo AC Costantini and Simone Priori</i>	181
Water induced soil erosion <i>R Jane Rickson</i>	193
Erosion by wind <i>John Tatarko</i>	208
Human exposure to aeroparticles emitted from unpaved roads due to traffic resuspension and wind erosion <i>Arón Jazcilevich and Ann G Wellens</i>	223
Soil salination processes and management <i>Uri Nachshon and Guy J Levy</i>	236
Degradation of soil structure and soil organic matter <i>Andrew S Gregory</i>	246
Drainage, soil water storage, buffering and filtering <i>Jeffrey Strock and Norm Fausey</i>	257
Environmental effects of irrigation <i>Sevilay Topcu</i>	266
Trade-offs of wastewater irrigation <i>Manzoor Qadir and Christopher A Scott</i>	277
Pollution and risks of trace elements in the soil environment <i>Peng Wang, Fang-Jie Zhao, and Steve P McGrath</i>	288
Pollutants—Persistent organic <i>Rai S Kookana and Divina A Navarro</i>	296
Pollution by microplastic in agricultural areas <i>Nicolas Beriot and Esperanza Huerta-Lwanga</i>	309

Municipal solid waste management: Production, management, and environmental effects <i>Bryant M Serre and Lynda H McCarthy</i>	321
Remediation of metals and organic contaminants in soil <i>Peter Sanderson, Md Mezbaul Bahar, Bhabananda Biswas, and Ravi Naidu</i>	333
Soil change under different scenarios	
Soil change under different scenarios <i>Joann K Whalen</i>	344
The effect of global change on the soil body <i>Sophie Cornu, David Montagne, and Antra Boca</i>	360
The effects of adequate and excessive application of mineral fertilizers on the soil <i>Bijay-Singh and Tek B Sapkota</i>	369
Foliar Application of Nutrients <i>Thomas Eichert and Victoria Fernández</i>	382
Mulches and cover crops part I: Types <i>KK Bandyopadhyay, CL Acharya, and KM Hati</i>	392
Mulches and cover crops part II: Role in soil health and climate resilient agriculture <i>KK Bandyopadhyay, CL Acharya, and KM Hati</i>	401
The potential agronomic and environmental applications of biochar: Prospects and challenges <i>Yu-Jun Wang, Ping Wu, Nanthi S Bolan, and Hai-Long Wang</i>	414
Soil management for carbon sequestration <i>Christopher Brock, Uwe Franko, and Martin Wiesmeier</i>	424
Soil tillage <i>Mathieu Lamandé, Lars Juhl Munkholm, and Trond Børresen</i>	433
Weed and soil management: A balancing act <i>Trevor Kenneth James and Charles Norman Merfield</i>	439
Terraces as traditional agricultural landscapes. Stability amidst change <i>Gerardo Bocco</i>	450
Soil quality protection policies and plans to ensure sustainability <i>Ram Swaroop Meena and Sandeep Kumar</i>	457
Construction of Technosols for green roofs and vertical green system <i>Eleonora Flores-Ramírez, Stefan Abel, Elizabeth Chávez-García, and Geoffroy Séré</i>	473
Management of park areas, sport fields, and school yards, including golf courses and public right of ways <i>Maxine J Levin and Anna Paltseva</i>	488
Soil-society relations	
Overview chapter on soil-society relations <i>C Siebe, Margaret A Oliver, and K Müller</i>	505
Soil art: Sensory and symbolic engagement with soils <i>Alexandra R Toland and Daniel Wolter</i>	509
Soil science in the criminal justice system <i>Lorna Anne Dawson</i>	521
Soil governance at the international, regional and national level <i>Harald Ginzky</i>	532
The economics of soils' contribution to human well-being <i>Bartosz Bartkowski and Julian R Massenber</i>	547

Soil and human health	555
<i>Margaret A Oliver and Eric C Brevik</i>	
Soil Science Education, Awareness and Outreach in the Modern World	572
<i>Laura Bertha Reyes-Sánchez and Eric C Brevik</i>	
Soils in landscape planning	580
<i>Seth Denizen</i>	

VOLUME 4: PEDOLOGY

Pedology

Pedology—Basic principles	1
<i>Rupert Bäumler, Uta Stockmann, and Margaret A Oliver</i>	

Factors of soil formation, pedogenic processes and mineralogy

Overview chapter on factors of soil formation	7
<i>Rupert Bäumler, Margaret A Oliver, and Uta Stockmann</i>	
Factors of soil formation: Climate	14
<i>Stefaan Dondeyne, Stephan Mantel, and Seppe Deckers</i>	
Factors of soil formation: Soil biota and organic matter as a factor for soil formation and weathering processes	25
<i>Scott Werts</i>	
Soil forming factors: Parent material	34
<i>Stephen Nortcliff</i>	
Parent materials: Loess	42
<i>Tobias Sprafke</i>	
Time	48
<i>Susan E Melzer, Caroline M Yonker, and Eugene F Kelly</i>	
Factors of soil formation—Human impacts	54
<i>Jonathan A Sandor, C Lee Burras, Michael Thompson, and Skye A Wills</i>	
Dynamic soils	69
<i>Markus Egli and Dennis Dahms</i>	
Interactions between soils and climate change	82
<i>Cornelia Rumpel</i>	
Primary minerals	91
<i>Balwant Singh</i>	
Mineral components of the soil clay fraction	109
<i>Darrell G Schulze</i>	
Short-range ordered aluminosilicates	121
<i>Tetsuhiro Watanabe, James B Harsh, and Rota Wagai</i>	
Metal oxides	135
<i>Andreas C Scheinost and Balwant Singh</i>	
Soil morphology	149
<i>Phillip R Owens and Zamir Libohova</i>	
Soil micromorphology	171
<i>Rosa M Poch and Georges Stoops</i>	
Soil Classification and distribution	
History and principles of soil classification	185
<i>Maria Gerasimova and Dmitry Konyushkov</i>	

Soil classification systems: World reference base and soil taxonomy	197
<i>David Badía-Villas</i>	
World reference base for soil resources (WRB)	206
<i>Stephan Mantel, Stefaan Dondeyne, and Seppe Deckers</i>	
World soil map based on soil taxonomy	218
<i>Eswaran Padmanabhan and Paul F Reich</i>	
Soils as archives of city history	232
<i>Hermine Huot and Jean Louis Morel</i>	
Classification of soils by ecozones	
Ecozones and soils – An introduction	246
<i>Rupert Bäumler</i>	
Cold Region Soils: Part I—Distribution, Properties and Processes	250
<i>Nicolas A Jelinski, Chien-Lu Ping, and John CF Tedrow</i>	
Cold region soils: Part II – Genesis and classification	263
<i>Nicolas A Jelinski, Chien-Lu Ping, and John CF Tedrow</i>	
Boreal forest soils	280
<i>Gabriele Broll</i>	
Soils of humid cool temperate regions	289
<i>Nicolas A Jelinski, Justin B Richardson, and Edward A Nater</i>	
Grassland soils in the cool–arid–temperate ecozone (Steppe, grassland)	299
<i>Mengyang You, Xiaobing Liu, Rupert Bäumler, and Margaret A Oliver</i>	
Soils from a warm-temperate semi-tropical ecozone (Mediterranean) with humid winter months	319
<i>J Torrent, Marco Pfeiffer, and Juan José Ibañez</i>	
Arid and semi-arid subtropical and tropical ecozone (II)	332
<i>Bernhard Lucke</i>	
Humid subtropical ecozone with emphasis on Acrisols and Alisols	343
<i>Nilton Curi, Sérgio Henrique Godinho Silva, and Alberto Vasconcellos Inda</i>	
Soils of the humid and sub-humid tropics	353
<i>Karl Stahr and Ludger Herrmann</i>	
Classification of soils by properties and environmental settings	
Sodic soils	368
<i>Guy J Levy and Uri Nachshon</i>	
Organic soils	383
<i>Heike Schimmel and Wulf Amelung</i>	
The pedology of anaerobic soils	398
<i>John Hollis and Allan Lilly</i>	
Alluvium and alluvial soils	417
<i>Janis L Boettinger</i>	
Hydric Soils	424
<i>MJ Vepraskas and JF Berkowitz</i>	
Wetland soils	436
<i>Cornelius Wilhelm van Huyssteen</i>	
Paddy soils: Characteristics, productivity and management	447
<i>Stephan M Haefele</i>	
Volcanic soils and non-volcanic andic soils	458
<i>Rupert Bäumler and G Uehara</i>	

PEDOMETRICS**Pedometrics**

- Overview of Pedometrics 471
Alexandre MJ-C Wadoux, Inakwu OA Odeh, and Alex B McBratney

Statistics and soil data analysis

- Statistics in soil science 486
Richard Webster

- Multivariate analysis for soil science 499
Si Yang Han, Patrick Filippi, Mercedes Román Dobarco, Januar Harianto, Mathew S Crowther, and Thomas FA Bishop

- Machine learning and processing of large data 509
Madlene Nussbaum

- The issue of scale and change of support in the spatial analysis of environmental data 521
A Castrignanò, A Belmonte, and N Romano

Soil measurements in space and time

- Sampling for soil survey 535
DJ Brus

- Handling of soil samples in the field, in transport to the laboratory and in the laboratory 551
Claudy Jolivet, Céline Ratié, Déborah Chavrit, Nicolas Soler-Dominguez, and Antonio Bispo

- Digital Soil Morphometrics 568
Yakun Zhang, Alfred E Hartemink, Jingyi Huang, and Budiman Minasny

- Proximal soil sensing in the field 579
Mikaela Tilse, Uta Stockmann, and Patrick Filippi

- Proximal sensing of soil moisture 591
Markus Tuller, Ebrahim Babaeian, and Scott B Jones

- Proximal sensing of land surface temperature 600
Ebrahim Babaeian and Markus Tuller

- Proximal sensing of evapotranspiration 610
Ebrahim Babaeian and Markus Tuller

- Remote sensing of soil moisture 618
Alexander Gruber and Jian Peng

- Remote Sensing of Soil Organic Carbon 631
Bas van Wesemael and Sabine Chabrilat

- Pedotransfer functions and their application to soil water dynamics 642
Marcel G Schaap, Yonggen Zhang, and Attila Nemes

Spatial and temporal soil variation

- Geostatistics: Modelling spatial variation 655
Richard Webster

- Uncertainty assessment of spatial soil information 671
Gerard BM Heuvelink and Richard Webster

- Digital soil mapping: Evolution, current state and future directions of the science 684
Brendan Malone, Dominique Arrouays, Laura Poggio, Budiman Minasny, and Alex B McBratney

- Geographical information systems (GIS) and soils 696
S Grunwald and J Böhner

- Precision agriculture 710
James A Taylor

Foundations, measurements and trends in pedodiversity <i>Juan José Ibañez and Marco Pfeiffer</i>	726
Soil landscape modelling	
Modeling soil development in a landscape context <i>Peter A Finke, Budiman Minasny, and Arnaud JAM Temme</i>	739
Climate and land surface models: Role of soil <i>Toby Richard Marthews, Holger Lange, Alberto Martínez-de la Torre, Richard J Ellis, Sarah E Chadburn, and Martin G De Kauwe</i>	751
VOLUME 5: SOIL PHYSICS	
Soil structure & mechanics	
Soil structure <i>Steffen Schlüter and John Koestel</i>	1
Aggregation <i>Teamrat A Ghezzehei</i>	8
Porosity and pore-size distribution <i>John R Nimmo, Sheela Katuwal, and Maik Lucas</i>	16
Pore-scale modelling of flow and transport phenomena in soils <i>Kirill M Gerke and Marina V Karsanina</i>	25
Soil texture: Its relevance, measurement and representation internationally <i>Attila Nemes</i>	35
Soil tilth <i>Thomas Keller, Douglas L Karlen, and Paul D Hallett</i>	48
Crusts and seals: Structural <i>Shmuel Assouline and Sally Thompson</i>	57
Soil mechanics <i>Markus Berli and Paul D Hallett</i>	69
Compaction <i>JJH van den Akker, L ten Damme, M Lamandé, and Thomas Keller</i>	85
Bioturbation—Physical processes <i>Siul Ruiz, Paul D Hallett, and Dani Or</i>	100
The reinforcement of soil by plant roots <i>Alexia Stokes and Anil Yildiz</i>	115
Physical effects of soil salinity <i>David Russo</i>	123
Shrink-Swell processes in soils <i>Pascal Boivin</i>	139
Water retention	
Water properties <i>N Lu, C Zhang, and D Hillel</i>	146
Water potential <i>Dani Or, Markus Tuller, and Jon M Wraith</i>	159
Water content and water potential measurement <i>Wolfgang Durner</i>	168
Soil water retention and characteristic curve <i>Markus Tuller and Dani Or</i>	187
Soil water repellency <i>Jörg Bachmann and Marc-Oliver Goebel</i>	203

Flow & transport processes

Aeration	216
<i>Rodney T Venterea and Dennis E Rolston</i>	
Capillarity	225
<i>Dani Or and Markus Tuller</i>	
Darcy's law	240
<i>Conrad Jackisch and Eva Kröner</i>	
Diffusion	247
<i>TKK Chamindu Deepagoda and Shoichiro Hamamoto</i>	
Hydrodynamics in soil	256
<i>Ty Ferre and Art Warrick</i>	
Thermodynamics of soil water	262
<i>Pieter H Groenevelt</i>	
Immiscible Fluids	271
<i>Yukie Tanino and Dubravka Pokrajac</i>	
Overland flow	287
<i>Tammo S Steenhuis, Rajith Mukundan, and Seifu A Tilahun</i>	
Direction-dependency of soil hydraulic and mechanical properties	294
<i>Steffen Beck-Broichsitter, Heiner Fleige, Jose Dörner, and Rainer Horn</i>	
Macropores and macropore flow	306
<i>Nicholas Jarvis and Mats Larsbo</i>	
Unstable preferential flow in porous media	314
<i>Naaran Brindt, J-Yves Parlange, and Tammo S Steenhuis</i>	
Leaching processes	321
<i>Brent Clothier and Steve Green</i>	
Colloid transport	336
<i>Yan Jin, Chongyang Shen, and Volha Lazouskaya</i>	
Scaling of transport properties	353
<i>Robert Ewing and Behzad Ghanbarian</i>	
Soil influence on groundwater	364
<i>David Rudolph and Edwin Cey</i>	

Thermal properties and behaviour

Temperature effects of soil hydraulic properties	379
<i>Jan W Hopmans and Robert Horton</i>	
Heat and vapor transfer	385
<i>Sunny Eng Giap Goh, Joshua L Heitman, and Robert Horton</i>	
Radiation Balance	393
<i>Jerry L Hatfield, Kaitlin Togliatti, Thomas J Sauer, and John H Prueger</i>	
Freezing and thawing cycles	400
<i>Alan W Rempel</i>	
Arctic permafrost	410
<i>Julia Boike, Andrey Abramov, Katrina E Bennett, and Lars Kutzbach</i>	
Permafrost and cold region hydrology	419
<i>Masaki Hayashi and Ylva Sjöberg</i>	

Sensing Techniques

Soil water sensing by neutron scattering	427
<i>Steven R Evett</i>	

Time-domain reflectometry	436
<i>GC Topp and Ty Ferre</i>	
Geophysical methods for soil applications	444
<i>Sarah Garré, Guillaume Blanchy, David Caterina, Philippe De Smedt, Alejandro Romero-Ruiz, and Nataline Simon</i>	
Non-invasive imaging of soil processes	459
<i>Craig J Sturrock</i>	
Hydrology & water balance	
Soil processes in the hydrologic cycle	469

Abstract

This chapter encompasses the basic principles of pedology, the study of soils in their natural setting. It provides basic information about the formation and properties of soils from any kind of parent material, the factors that influence soil formation at the Earth's surface, the induced processes, and the role of soils in the environment.

Key points

- Factors of soil formation—climate, landscape, vegetation, parent material and human influences.
- Translocation and transformation processes.
- Origin, development, properties, soil threats.

Introduction

The interest in soils goes back to Mesolithic and Neolithic times when humans recognized that soils provide food for life, but are different from place to place. Our ancestors observed that plants grow well at some sites, but not at others. They became aware of differences in soil colors, particle sizes, or moisture conditions at these sites, and tried to identify advantages. With increasing population in different regions of the world, with environmental fluctuations, and in combination with the domestication of wild animals and sedentism the pressure on soils and the need to gain knowledge about soils gradually increased.

Pedology is the study of soils in their natural setting and has at times been equated with the study of soil genesis and soil classification. The people who study soils are pedologists. Pedologists integrate understanding of landscapes, vegetation patterns, climate, and human activity into knowledge about soils, their distribution, mode of formation, and value in different contexts. Pedologists also extrapolate information from one scale to the next, to create a coherent model of soils from microscopic observations to the landscape scale. Integration and extrapolation are necessary because soils form a highly variable continuum over the Earth's surface.

Pedology

The term pedology derives from the ancient Greek terms 'πέδον' which means soil (pedo) and '-λογία' now 'ology' meaning the study of something. The International Union of Soil Scientists (IUSS) interprets pedology as the overall scientific study of the soil. Pedology embraces the scientifically based research of soils that provides information about soil morphology, the processes involved during soil formation, the physical, chemical and biological properties to increase our overall knowledge on soils. The

Fig. 1 Illustration of the pathways of soil formation, from the factors to processes and finally to properties of soils.

importance of soil and its study is emphasized by the fact that soils belong to the essential natural resources for all life on our planet that also include water and air.

Pedology includes ‘pedogenesis’, the study of the origin and formation of soil as a natural body, the spatial and vertical distribution of soil in the landscape which includes classification, and interpretation of soil properties for soil use and its management. The topic emerged in the natural sciences in the 19th century. A German scientist Albert Fallou introduced the term in 1862 (Singer, 2005). Early pedology focused on the description and mapping of soil, whereas today it embraces a complex subject covering many sub-disciplines such as soil chemistry, physics, biology, microbiology, ecosystem services, pollution and contamination, and agricultural management and sustainability.

Basic questions on the study of soils are: What are soils? How do they form? What kind of processes are present? What are its properties? What is the role of soils in the environment? What are the threats to the soil resource?

Many attempts have been made to define soils (Hartemink, 2016). Soils are the thin layer on top of the Earth’s surface including semi-terrestrial and sub-hydric soils. Their global mean thickness is about 60 cm. Soils represent the interface of the lithosphere, hydrosphere, atmosphere and biosphere. They serve as the habitat of plants, animals, insects, bacteria, fungi, and humans. Soils are the conversion product of mineral and organic matter under the influence of highly variable environmental factors like climate, biota, landscape morphology and dynamics, parent materials, and time (Fig. 1).

These main factors of soil formation vary from place to place and with time. Any soil profile (i.e., the vertical surface of a soil) and any sample of soil material or soil horizon is therefore unique in their properties. Soils are multi-dimensional objects with overlapping and interacting solid, liquid and gaseous phases, which explain the complexity and heterogeneity of and within soils. The complexity of soils makes their classification, mapping, or modeling of processes challenging (Phillips, 2017; Mikhailova et al., 2021). Classification, for example, is an essential tool of scientific disciplines. It enables soil information to have a structure so that people in many spheres can work with soils, to create soil maps, to assess the land-use potential not only for food and crop production but for many other wildlife and human needs, and to identify threats.

The complexity and polygenetic nature of soils is shown in Fig. 2. The soil profile is an assemblage of fossil soils developed in pyroclastic materials of Holocene volcanic eruptions covering a morainic soil of Late Pleistocene age. Each fossil soil represents a period of soil development before interruption and burial with new material. The soil profile is therefore a good example of the complexity, but also the ‘memory’ of soils that allows reconstruction of the history of volcanic eruptions, landscape evolution, and time-related periods of soil formation (Targulian and Bronnikova, 2019).

Soil formation (pedogenesis)

Soil formation is a dynamic process towards quasi-equilibrium stages of soil development. The input of energy and matter is essential to transform parent materials to soils. Parent materials include solid rocks, mineral and or organic sediments, or (artificial) material of human origin like waste or concrete (Howard, 2021). Considering a block of solid rock like granite, the block is at an equilibrium stage without changes as long as it is surrounded by granite. Weathering starts as soon as the block is exposed at the Earth’s surface to a completely different environment with temperature fluctuations, moisture fluctuations, and exposure to oxygen. The rate at which weathering occurs is influenced by the chemical and mineral properties of the parent material itself. For example,

Fig. 2 Example demonstrating the complexity of soils: Gelic Andosol on top of Late Pleistocene moraine deposits in S-Kamchatka (Photograph by R. Bäumler).

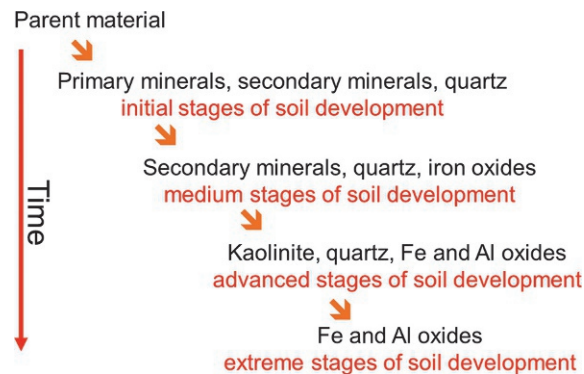

Fig. 3 Schematic diagram of soil development stages under a leaching environment from initial to advanced soil development or weathering (*Fe, iron and Al, aluminium).

porosity, mineral size, crystal structures or specific surface area of parent materials are important factors. Combined, physical and chemical weathering are both highly effective to drive soil formation, with physical weathering causing the disintegration of parent materials such as rocks without chemical changes, and chemical weathering causing the fractional or total dissolution of minerals. Therefore, soil formation might be seen as an equilibration of matter under a dynamic environment at the Earth's surface.

Under a leaching environment (i.e., precipitation exceeds evaporation), for example, pedogenesis proceeds until steady-state conditions from initial stages to advanced or extreme stages of soil development are reached (Fig. 3). The first step in soil development is the disintegration or decomposition of primary minerals that form new minerals, so-called secondary minerals. They form from the dissolution products such as clay minerals and pedogenic oxides, which accumulate with time as long as the soil forming processes are active. Interruptions to these processes might be induced by tectonics, climate change, soil erosion, land-use, man-made or natural coatings with new material including concrete sealing.

Fig. 4 Initial soil development in moraine deposits of the F urkeleferner glacier, Martell-Valley, South Tyrol, N-Italy (Photograph by R. B aumler, taken 2019).

Fig. 4 shows an example of initial soil development in moraine deposits directly after retreat of the F urkeleferner glacier situated in the Martell Valley in South Tirol, Italy. The ablation moraine parent material shows signs of extreme wetness from the recently melting ice. Hydromorphic features caused by oxidation processes can be seen as initial signs of soil development in the top few centimeters of the soil profile. It is noticeable that the soil is still free of organic matter.

Fig. 5 shows an example of a well-developed soil. The soil profile shown represents an intensively weathered fossil Ferralsol/Oxisol of at least Middle Pleistocene age developed in phyllite, and covered by a Cambisol of 70-cm depth developed from eolian deposits of Late Pleistocene origin. Optically stimulated luminescence (OSL) dating of the eolian deposits at 65 cm of depth categorized these to be of a minimum age of 46 ± 5 ka (GI-32; Dorji, 2016). The near-surface overall enrichment of oxidic iron and aluminium compounds and clay minerals of the kaolinite group that form lateritic bauxite deposits might be representative of the final stages of weathering and soil formation. However, a final soil formation equilibrium stage is possibly questionable, because soils represent biogeochemical reactors with process-response-reactions that can result in reversible and irreversible changes in a dynamic environment (Lin, 2011).

Transformation and translocation processes of matter and energy are the main processes that occur during the development of a soil profile. Transformation processes include, for example, the decay and accumulation of organic matter, the weathering of primary minerals into secondary minerals and the formation of pedogenic minerals from weathering products. Organic compounds are added to the soil profile through litter, and are transformed to soil organic matter mainly by soil biota to gain nutrients and energy. Organic compounds might be completely decayed through processes of mineralization with the release of CO_2 , nutrients and water, or might be partly decayed and accumulated in the soil profile as organic matter by the process of humification.

Interactions of pedogenic minerals, organic compounds, biota exudates and water result in a unique soil structure, a complex three-dimensional mixture of matter with voids in-between, so-called pores, and also result in the formation of unique soil layers known as soil horizons (Hartemink et al., 2020; Matus, 2021). Soil pores can be filled with soil solution (i.e., the liquid phase with water and solutes) or gases (i.e., the gaseous phase). Coarse and middle-sized pores, in turn, are the living environment of soil biota, and are responsible for drainage (coarse pores) or water storage (medium pores). All soil forming processes can proceed consecutively or together at the same time. Changes in any of the regulating factors will immediately induce transformations within soils and the surrounding environment.

Soils are open systems. Matter and energy can be mobilized, transported by leaching, interflow, capillary rise or diffusion. The soil system includes gases, ions (nutrients), water, organic particles, colloids, pollutants. It may lead to a total loss or to a gain by input or immobilization and accumulation of matter within specific parts of the soil such as the formation of eluvial and illuvial horizons during the process of podzolization, argillization, or the accumulation of salts and the formation of soil crusts in dry areas.

Humans (biota) are considered part of the soil forming factors. Human activities have influenced soils and soil formation since the so-called Anthropocene (Amundson, 2021; Howard, 2021), with most soils and their characteristics being changed by human

Fig. 5 Fossil soil developed from phyllite and covered by eolian deposits, Paro valley, Bhutan (Photograph by R. Bäumler).

influence. Negative human influences are the result of intensive land use (soil compaction, monocultures, misuse of pesticides, salinization by irrigation mismanagement), the production of greenhouse gases, deforestation and over-grazing inducing desertification and soil degradation, urbanization (sealing of soils), legal and illegal mining activities, waste production and deposition.

Importance of pedological research

Soils are essential for terrestrial biogenic life. More than 90% of all insects, for example, have a geobiotic growth stage. Knowledge about processes and properties of soils are therefore essential with respect to the role of soils in the environment, i.e. energy, water and element (nutrients) cycling, home of life. Pedological research provides information about soil-landscape interactions, soil-plant interactions, soil-human interactions, nutrient supply or deficiency, the behavior of solutes and solids including harmful compounds like neonicotinoids and other pesticides, elements and organic compounds at toxic concentrations. Those toxic compounds might be generated during the natural biodecay of soil organic matter of originally non-toxic compounds. Pedological research provides the theoretical framework for classification, mapping, modeling, land-use potential, food supply, risk assessment, ecosystem management in a changing environment. Information is needed about temporal and spatial aspects with respect to the behavior of hazardous compounds like greenhouse gases. Almost all important parameters and properties can be measured or observed in the field or in the laboratory, or with the help of remote sensing techniques to answer questions about source, storage, decomposition, translocation or sorption in any of the soil compartments.

Concluding remarks

Soils are a complex multi-dimensional natural materials with still many unknown variables. Recent studies of soils go beyond qualitative analysis towards quantitative research and modeling of processes (Minasny et al., 2008) including energy and mass transfer (Amundson, 2021). Organic compounds with complex structures are still partly unknown. Only a fraction of soil microorganism species and their role in the pedosphere is well known. Manifold threats affect soils like extensive land-use, overgrazing, deforestation, salinization, acidification, soil erosion, desertification, contamination, or ground sealing. Increasing pedological knowledge may help to gain greater insight into soils and avoid or reduce such threats.

Soil protection should therefore be one of the most important social and political responsibilities of the 21st century for a sustainable use of soils, a material, which—once destroyed—is not reproducible even within multiple human life spans.

Abstract

Dokuchaev first introduced formally the concept of factors of soil formation, which act and interact at different spatial and temporal scales. This chapter provides an overview of these factors, which is followed by chapters on most of the specific factors. Climate has a major effect on soil formation because it affects the weathering of rocks and the mineral soil, and vegetation and organisms, which play a major role in changing rocks and sediments to soil. Parent material underpins soil particle-size distribution, chemistry and physics. Relief affects soil hydrology and human use of the soil. Finally, human influence on soil formation has now been recognized as a factor.

Key points

- The four factors originally suggested by Dokuchaev have now become six
- The original factors were climate, parent material, vegetation and biota, and time
- The next development added relief
- Finally, it is now considered that a further factor, humans, should be included to reflect major changes to soil by humans

Introduction

This chapter provides an overview of the chapters in the section on factors of soil formation. Soil, the thin outer skin of the Earth's land, is a critical and fragile natural resource. It is the basis for almost all global agriculture and the medium in which most terrestrial biological activity occurs. Here, we introduce the five forming factors of soil originally suggested more than a century ago (parent material, time, climate, topography, and organisms) and updated over the years to add human activity as the sixth forming factor, namely anthropogenesis (Dror et al., 2022). The major soil forming factors have a profound effect on the types, processes, properties and regional distribution of the soil resource that we observe. The diversity of soils over the Earth's surface results from the site-specific interaction of these factors during soil development.

Dokuchaev (1883), the founding father of soil science as we know it today expressed the relation between the factors of soil formation simply as:

$$s = f(cl, p, v)^t,$$

where s = soil, cl = climate, p = parent material, v = vegetation and biota. The superscript ' t ' indicates that these relations change with time. Nortcliff (2023) notes in his chapter in this section that Hilgard (1914) in the USA and Crowther (1930) in the United Kingdom continued to consider the factors of soil development based on environmental interactions. In addition, Shaw (1930) from the USA also considered a model of soil formation, but did not develop his model further before he died suddenly in 1939. Jenny (1941) then developed these ideas further with the concept that the state of the soil system depends on the interaction of independent variables or soil forming factors. These are represented in his now famous general 'clorpt' formula:

$$S = f(cl, o, r, p, t, \dots),$$

where 'S' is a property of the soil, (f) is a function of: 'cl' is climate, 'o' now represents vegetation and living organisms (macro- and micro-biota), 'r' is relief or topography (this will affect the hydrological regime), 'p' is parent material (material on which the factors have acted to form soil) and 't' is time (how old the soil is). With the increase in human activity and humanity's effects on soil development, a factor related to mankind in the era of the Anthropocene has now been considered to be added to the factors of soil formation.

The factors and their interactions define the state of the soil system. The soil is an open system with incoming and outgoing fluxes of energy and matter in all directions. These include incoming and outgoing radiation, gases moving by mass flow, water in liquid and solid forms, solids dispersed in air or dissolved or dispersed in water, and organisms that migrate through the system.

In addition to the inherent complexity of each of the soil formation factors, they act and interact at different spatial and temporal scales. For example, there are broad climate belts that operate at the scale of tens to hundreds of kilometers, but there are also microclimates that act over tens of centimeters. These differences in scale further transmit to vegetation and organisms, and might also impinge on the time factor. It is notable that different types of soil may form from the same parent material depending, in particular, on the climate and vegetation. Soil development is a slow process with changes taking place over long time periods, which has implications for the damage caused by human activities. Once destroyed, soils are considered a non-renewable resource within the timeframe of generations.

Practical problems related to the complexity of the interactions between factors and scale issues include difficulty in the development of soil classifications that can communicate information at different spatial scales, climates, vegetation and countries. There are many worldwide classification systems and they are often limited by scale issues. In the early Russian and North American soil classifications, the different scales of influence of the soil forming factors were identified in the broad structure of the classification systems (Nortcliff, 2023). Increasingly, the interrelationships between the soil forming factors and their influence on the nature of soils have been recognized as more complex and variable with more subtle relationships at scales from hundreds to tens of kilometers, and at even smaller scales as understanding progressed.

Parent material

Within the suite of soil factors, parent material forms the basis from which soils develop and is considered the initial state of the soil system. Thus, parent material is one of the key factors that underpins soil formation (Nortcliff, 2023). Most parent materials are mineral matter, although there are distinctive soils that developed from organic materials. The first stages of soil development involve the weathering of minerals, and in young soils parent material is a major influence on their nature that is independent of other factors. In most soils this influence reduces through time. The parent materials may be in situ geological materials or eroded and redeposited materials. Parent materials might therefore be solid rock, unconsolidated unweathered or pre-weathered materials or sediments, with or without carbonates. Mineral structure (crystallinity), grain sizes (surface area) and chemical composition in turn influence resistance to weathering or rate of soil development, and almost all physical and chemical soil properties such as the content and release of nutrients. Fig. 1 shows a Leptosol (WRB)/Entisol (Soil Taxonomy) from diabase rock under a temperate climate in Middle Europe. The photograph clearly indicates the weathering front along the rock cracks.

One of the most important groups of agricultural soils, Mollisols (Soil Survey Staff, 2022) or Chernozems (World Reference Base for soil resources, WRB, 2022), have formed largely on redeposited wind-blown material known as loess (Sprafke, 2023). Loess has formed largely at the margins of the world's major ice sheets of the Quaternary period and covers about 10% of the Earth's surface, now mainly in the temperate zone. Silicate silt predominates over carbonate, together with clay and some fine sand, making loess a favorable soil parent material.

Climate

Climate (Dondyene et al., 2023) is an important factor; it determines the rates of weathering, chemical reactions, transport of matter and biological activity in soils. Therefore, it is not surprising that the earliest soil scientists categorized and mapped soils according to climatic zones or conditions (Hartemink and Bockheim, 2013). This led to the concept of 'zonal soils,' i.e., soils that are in equilibrium with climate and vegetation in different latitudinal zones, which was introduced by Dokuchaev in the 1880s. Solar radiation, precipitation, temperature, and wind are the key climatic components in relation to the formation, properties and hydrology of soils. Solar radiation determines the net energy influx and varies according to latitude and season, and determines the temperature. Temperature and temperature fluctuations influence physical weathering (frequency of frost changes; Fig. 2) and the kinetics of geochemical and biochemical reactions (catalytic accelerator). Wind affects the fluxes through soil and can cause soil erosion (abrasion), transport, and deposition of fine-grained particles. Evapotranspiration potential depends on temperature and wind; it includes the water transpired by plants, water that evaporates from water bodies, surfaces and the soil, and sublimation from snow or ice. The net water flux in soil, i.e., the balance between infiltrating water and evapotranspiration, determines the movement of soluble elements and ultimately the soil's water content and the nutrition of plants. Understanding the soils' potential for agriculture, environmental functioning, and climate change mitigation and adaptation requires insight into their relation to climate.

Biota

In terrestrial environments, soils are the primary interface between geology and biology (Werts, 2023), and without the biological component the surface deposits cannot be classified as soil in a pedo-ecological sense. Biology has various influences on soil properties with depth resulting in a notable transition of biological activity from the top- to sub-soil along horizon boundaries (Fig. 3). Biological activity leads to the incorporation of organic matter in the topsoil and the amount gradually decreases with depth, in general. Much of the organic matter in soil derives from the input of above- and below-ground vegetation, the latter in the form of root systems. The initial breakdown of material can begin with microorganisms such as fungi, bacteria and lichens, and by vertebrate species such as birds, reptiles or mammals and invertebrate detritivores, herbivores, and carnivores such as earthworms, millipedes, termites, insects, snails and so on. In addition, organic matter derives from root exudates and necromass from microorganisms. The abundance and influence of each of these groups varies with climate in terrestrial environments and provides the foundation for the changes in ecosystems that we can observe in the major ecozones. Consequently, biological influences also change with temperature, latitude, water availability, and human influence.

The huge number of different organic compounds in the soil dwarfs the variety of minerals present and can often be very difficult to identify (Werts, 2023). The soil biology also has a major effect on the plant nutrients present, soil structure and hydrology. It is probably the most complex of the soil factors because of the many components, their interactions with soil minerals, water, roots, gases and themselves. There has been a huge increase in interest in soil biology with the relatively new omics techniques and more feasible methods to determine the DNA of soil biota. These techniques should enable the identification of new antibiotics that are still unknown from the potentially large reservoir provided by soil microorganisms and their exudates.

Relief, topography

The influence of topography on soil formation from macro to microscales is not described in detail in a separate chapter despite its significance especially in hilly and mountainous areas. Finke et al. (2023; in this Encyclopedia) consider landscape evolution models as a means of understanding the relations between relief and soil formation. Relief or topography plays an important role in soil formation through steepness of the slope, degree of departure from the horizontal and elevation, and aspect, direction the slope faces relative to the sun. Relief affects both vertical and horizontal soil processes and their rates of action. Slope affects the degree of movement of soil across the surface, fluxes through the soil and soil development. Where the slope is gentle or almost level, the soil shows the greatest relative development. The steeper is the slope, the greater is the movement of material along it by gravity. Heavy rain or permafrost conditions may cause erosion or solifluction of the soil at hilltop and slope positions downhill with accumulation at the foot of the slope or valley bottom. These mobilization processes depend strongly on the material properties of the soil particles and are additionally enhanced by increasing slope angles, a lack of vegetation, and insolation of the slopes. Slope and elevation also affect soil drainage and depth to the water table, which in turn affect soil formation. This is reflected in the nature and extent of horizon development. A series of soils that develops along a hillslope on the same parent material and climate is described as a Catena. Along a Catena, deeper well-drained soils occur in summit positions, thinner well-drained soils are present on the slope and deeper sometimes poorly-drained soils can be found in the footslope positions. Aspect affects insolation so that in the northern

Fig. 4 Colluvisol from Late Pleistocene deposits near Berlin, Germany (A), and (B) solifluction after thufur (icelens) formation under the influence of permafrost at low slope angles, northeastern Iceland. Photographs by R. Bäumler.

hemisphere the north side of slopes tends to be cooler and wetter with slower rates of soil chemical and biological processes, and more vegetation growth, whereas south facing slopes tend to be warmer and drier with faster rates of soil processes. The reverse is the case in the southern hemisphere.

Fig. 4 gives two examples of soils influenced by topography. Fig. 4A is a so-called Colluvisol, a fossil soil successively covered by eroded soil from upslope during the Holocene, and Fig. 4B shows a soil displaced by solifluction under permafrost conditions in northeastern Iceland at low slope inclination.

Time

The environmental conditions under which soils and their properties develop, are governed by combinations of the above factors, which operate over time (Melzer and Yonker, 2023). Climate, biota, topography, and parent material have a direct effect on soil-forming processes, whereas time has an indirect effect. Time affects soil-forming processes and the degree of soil development by controlling their duration. Thus, we can differentiate between ‘young,’ ‘intermediate’ and ‘old’ soil in each ecosystem based on degrees of chemical and physical weathering and the resulting expression of soil properties (Fig. 5). The amounts and distribution of soil organic carbon (SOC), carbonate, and other key elements, and the amount and distribution of clay and its mineralogy change as a function of time in a generally consistent and predictable manner (Koop et al., 2020).

The amounts and distribution of the soil constituents above are often used to determine the relative age of a soil with sufficient accuracy despite the heterogeneous soil matter (Dorji et al., 2009). Older soils in general have more fine particles and clay minerals, larger contents of pedogenic oxides and a greater accumulation of SOC than younger soils. The accumulation of SOC eventually reaches a steady state where inputs equal outputs, and there is no further net accumulation with increasing soil age (time) (Lawrence et al., 2015; Wang and Amundson, 1996; Merritts et al., 1991). The length of time needed for SOC to reach a steady state varies among environments, but is within a relatively short time frame of 10^2 – 10^3 years (Buol et al., 1997).

The accumulation of calcium carbonate (CaCO_3) in soils over time is limited in general to soils of semiarid and arid regions, where carbonates precipitate in dry soil environments, with high pH, and high evapotranspiration (see also Fig. 3). Unlike SOC, CaCO_3 accumulation may not reach a steady state, but continues to increase through time (Wang et al., 2016; Monger and Rachal, 2013).

The most abundant elements in soils, excluding oxygen and carbon, are silicon, aluminum, iron, magnesium, calcium, sodium, and potassium, and their relative abundance is a direct function of the degree of soil weathering (Dixon and Weed, 1989), which increases or decreases through time and soil development (young, intermediate, old).

The human factor

An important question now arises because of the human influence on soils that has been ongoing for many centuries. The question is “Are humans part of the ‘Biota’ factor or should they be considered an independent additional ‘anthropogenesis’ factor of soil formation as suggested by Dror et al. (2022), especially if we acknowledge the Anthropocene as the present era” (Sandor et al., 2023).

Fig. 5 Fossil soil covered by a Cambisol of about 65 cm depth developed from terminal moraine deposits of the Djol Djilga glacier. The soil formation was stopped 8000 years BP, the fossil A horizons was dated by ^{14}C . Photograph by R. Bäumler.

Soil formation can be strongly influenced by any kind of anthropogenic land-use activities or land-use changes that interact with or can override the natural factors of soil formation. This influence can extend to a total interruption of soil formation, for example, by soil sealing. Human activities that influence the state of the soil include, for example, mining, urbanization, agriculture and horticulture, forestry or deforestation, road construction, military training areas, terracing and many other activities. These result in the input of matter (industrial and organic fertilizers, lime, pesticides, technogenic materials, or irrigation water), mixing of the natural sequence of soil horizons (Fig. 6), the loss and degree of re-deposition of soil by wind or water erosion, the deposition of any kind of material on top of the natural soil (construction debris, disposed waste, landfill), a human induced loss or decay of soil

Fig. 6 A deep ploughed site (trenching) in eastern Romania for amelioration, afterwards covered with spoil debris. Photograph by R. Bäumler.

organic matter, or the neoformation of soils exclusively by human activities (Anthrosols, Terra preta; Glaser and Woods, 2004). Another issue to consider under the human factor is the contamination of soils with compounds mainly generated by chemical industries (pesticides, microplastics, herbicides), either localized or over larger areas, or more diffuse. These inputs might be intentional or accidental, and are often toxic or with unknown toxicity, which negatively affects processes and properties of soils and soil biodiversity.

Abstract

Climate determines the rates of chemical reaction, substance transport and biological activity in soils, therefore, the earliest soil scientists categorized soils according to climatic zones. Understanding the soils' potential for agriculture, environmental functioning, and climate change mitigation and adaptation requires insight into their relation to climate. The Soil Orders (Soil Taxonomy) and the Reference Soil Groups (World Reference Base for soil resources) that typically occur in each climatic zone are discussed and underlying processes of soil formation are explained. Finally, the effects of global climate change on soils are discussed, as well as evidence in soils of past climatic changes.

Key points

- Climate is a key factor in the formation of soils
- Major soils and soil-forming processes are presented for each climatic zone
- Understanding the relationship between climate and soils is key to assessing land-use potential, including their potential for carbon sequestration, climate change mitigation and adaptation
- Soils are recorders of past climate changes

Introduction

Climate is a key factor in the formation of soils and it also determines the potential for land uses. It controls the rates of chemical reaction and substance transport in soils, and directly affects the flora and soil fauna. The climate influences human land uses by regulating the duration of growing seasons and the kind of crops that can be planted. Furthermore, soils also serve as climatological archives, as their properties not only reflect current but also past climatic conditions. These examples demonstrate the complex relationship between soils and climate. While the human world population is expected to increase further from the 7.7 billion reached in 2019, to over 10.9 billion by 2100 (United Nations and Department of Economic and Social Affairs, 2019), global climate change is posing unprecedented challenges to human societies (IPCC, 2022). In this context, insight into the relationship between climate and soils is important, to understand the soils' role in agricultural and environmental functioning and, to be able to assess their potential for climate change mitigation and adaptation.

Solar radiation, precipitation, temperature, wind, and evapotranspiration are the key climatic components in relation to soils. Solar radiation determines the net energy influx and varies according to latitude and season, and determines the temperature. Temperature and temperature fluctuations influence physical weathering and the kinetics of geochemical and biochemical reactions. Wind contributes to processes of soil erosion and deposition and, together with temperature, also determines the evapotranspiration potential. Evapotranspiration is the water transpired by plants combined with water that evaporates from water bodies, surfaces and the soil, as well as the sublimation from snow or ice. The net water flux of water in the soil, the balance between infiltrating water and evapotranspiration, determines the movement of soluble elements and ultimately the soil's water content.

Given the strong influence of the climate on soil properties, it is not surprising that the first attempts to classify and map soils were referring to climatic conditions (Hartemink and Bockheim, 2013; Sibirtsev et al., 1898) (Table 1). The concept of 'zonal soils,'

Table 1 Soil zones of Europe following Dokuchaev's concepts and with corresponding Soil Orders of Soil Taxonomy (Soil Survey Staff, 2014) and Reference Soil Groups of WRB (IUSS Working Group WRB, 2015).

Soil zone	Soil order	Reference soil group
Polar-Tundra soils	Gelisols	Cryosols
Sod-Podzolic soils of taiga forest	Spodosols, Histosols, Glossudalfs	Podzols, Histosols, Retisols
Grey forest soils	Alfisols, Glossudalfs, Mollisols	Luvisols, Retisols, Phaeozems
Chernozems and steppe soils	Mollisols	Chernozems, Kastanozems
Desert soils	Aridisols	Solonchaks, Solonetz, Gypsisols, Calcisols
Red-earth laterite soils	Ultisols	Chromic Luvisols, Lixisols, Acrisols, Nitisols

Soil zones adapted from Sibirtsev NM, Ferkhmin AR, and Tanfiliev GI (1898) *Schematic Soil Map of European Russia* [in Russian].

i.e., soils that are in equilibrium with climate and vegetation in different latitudinal zones, was introduced in the 1880s by V.V. Dokuchaev (Rusakova et al., 2022). It was also realized that at the fringes of each zone, soils with intermediate characteristics occurred which were referred to as 'intrazonal' soils. Furthermore, where soil formation was limited, soils occur that are not particularly typical for any zone, e.g. soils of recent river or wind deposits were called 'azonal' soils.

Between the Tropics of Cancer and Capricorn the sun's rays reach Earth at a steep angle, up to an angle of 90° at noon twice per year. The intertropical, low latitude, zone benefits from a radiation surplus, while the polar, high latitude, zones experience a deficit. As a result, seasonal thermal variations are low in the intertropical zone, while these are high in polar and mid-latitude zones. These variations in temperature, in conjunction with air and oceanic currents, lead to a zonal pattern of climate and vegetation varying from warm and humid around the equator where rainforests occur, to warm and arid around the Tropics of Cancer and Capricorn where deserts occur, and cold in the sub-arctic and arctic zones with tundra vegetation. In the European part of Russia, Belarus and Ukraine, the fairly uniform gradient of sediments, ranging from sandy in the north to silty in the south, coincides with a temperature and precipitation gradient. In the late 19th Century, V.V. Dokuchaev observed that this climatic gradient is reflected in a sequence of vegetation zones, to which particular soils are associated (Table 1). On his map of the soils of the northern hemisphere, Dokuchaev indicated five zones: boreal, taiga, Chernozem, aerial and lateritic zones (Rusakova et al., 2022), with which he applied the principal of zonation for mapping and classifying soils at world level in direct relation to climate.

The vegetation and soils in North America, however, do not occur in such latitudinal zones. Although the parent material is also quite homogenous over fairly large areas, the precipitation decreases from the east coast to the interior, i.e. perpendicular to the north-south temperature gradient. As Chernozems, Chestnut brown soils and Desert soils all occur at the same latitude as Brown forest soils and Podzols, it is difficult to apply the concept of zonal soils in North America. During soil surveys in the USA in the 1930s soil groupings were based on soil properties and broad environmental conditions. Only the highest category (Category VI, Solum Composition Groups), the distinction between the Pedocal (soils with accumulated lime) and Pedalfer groups (lacking secondary lime) reflects a relation with climate: where precipitation is lower than evapotranspiration, secondary lime will accumulate versus where precipitation is higher than evapotranspiration, lime will dissolve and leaches.

In Soil Taxonomy, the American classification system introduced in the 1970s, soils are classified based on directly observable and measurable properties. At the second level of classification, climatic characteristics are taken into account because it is based on soil moisture and soil temperature regimes. These soil climatic criteria correlate with the global climatic zones. For example the xeric soil moisture regime (i.e., total soil moisture control section is, in normal years, dry for 45 or more consecutive days in the 4 months following the summer solstice and moist for 45 or more days in the 4 months following the winter solstice) is typical for Mediterranean climates (moist and cool winters, dry and warm summers). Similarly, the (iso)hyperthermic soil temperature regime (i.e., mean annual soil temperature at 50-cm depth is 22 °C or higher; 'iso-' indicating a temperature fluctuation of less than 6 °C which is typical for tropical climates).

The relation between climate and soils is further presented following climatic zones based on the aridity/humidity index (AHI) and combined with four temperature regimes (Fig. 1). We discuss the soils that typically occur in each climatic zone following the 12th edition of *Soil Taxonomy* (ST) (Soil Survey Staff, 2014) and the third edition of the *World Reference Base for Soil Resources* (WRB) (IUSS Working Group WRB, 2015). The AHI, as proposed by the United Nations Environmental Programme (UNEP, 1992), is calculated as the ratio between the average annual precipitation (P) and the reference (or potential) evapotranspiration (ET₀). Six climatic zones can be recognized using the aridity/humidity index, ranging from hyper-humid (AHI > 2), predominantly around the equator, to hyper-arid (AHI < 0.05) mostly around the tropics. Agro-ecologically it is more relevant to define the intertropical zone as the area where average monthly temperature corrected to sea level, is always more than 18 °C (isomesic to isohyperthermic in ST), rather than just considering the latitude (FAO, 1978). Similarly the Arctic and subarctic can be defined as the area where monthly temperatures are above 10 °C for at least one and at most 3 months of the year (subgelic to hypergelic, in ST) (<https://arcticportal.org/maps/download/arctic-definitions>). The mid-latitudinal zones can be further divided into a cold temperate zone, where during summer the soil temperature does not exceed 8 °C (frigid and cryic, in ST) and a warm temperate zone where soil temperature does not exceed 22 °C (mesic to (hyper)thermic, in ST).

Fig. 1 Climatic zones of the world based on the UNEP aridity/humidity index. Note the north–south zonation in Eurasia, Asia and Africa vs the east–west zonation in the Americas. The tropical isotherm shows the area where average monthly temperature is more than 18°C, when corrected to sea level. In the subarctic, temperatures are above 10°C for at least one and at most three months of the year. The temperature zone can be divided into a cold zone (soil temperature is <8°C) and a warm zone. Authors' map based on Global Potential Evapotranspiration and Global Aridity Index - <https://cgicarsi.community/>.

Soils in humid and sub-humid tropical climates

Tropical climates have an average temperature, corrected to sea level, above 18 °C in every month (isomesic, iso(hyper)thermic, in ST). In most of the areas around the equator, annual rainfall is high and exceeds the annual evaporation (Fig. 1).

High precipitation combined with high temperature in the hyper-humid and humid tropical climates, results in intense, deep chemical weathering and strong leaching of solutes in the soil. Silicates are weathered by water and CO₂ (carbon dioxide) that produces dissolved silica (H₄SiO₄) and bicarbonate, which are removed with percolating water. This process is called desilication (Van Breemen and Buurman, 2002). Primary minerals such as feldspars and micas are dissolved or transformed into kaolinite (Al₂Si₂O₅ · 2H₂O), goethite (α-FeOOH), and gibbsite (α-Al(OH)₃). In some cases lepidocrocite (γ-FeOOH) may be formed. This process of ferralitization is widespread in the warm hyper-humid, and humid tropical regions particularly on old geomorphic surfaces. It gives rise to acidic soils with low cation exchange capacity (CEC < 16 cmol_c kg⁻¹ clay) due to the prevalence of low-activity clay, and soils with variable charge occur where iron and or aluminum hydroxides are dominant. Such soils are known as Oxisols (ST) or Ferralsols (WRB) (Fig. 2A), and kandic Great Groups of the Ultisols (ST), which in part fall under the Acrisols (WRB). On relatively younger deposits, and younger, more dynamic geomorphic surfaces, chemical weathering of primary minerals produces large amounts of exchangeable aluminum, resulting in Paleudults (ST) or Alisols (WRB). In sandy deposits, strong leaching can lead to the formation of giant Spodosols (ST) or Podzols (WRB) (Fig. 2B).

In hyper-humid and humid climates, often in combination with oligotrophic conditions, undecomposed or incompletely decomposed organic matter accumulates in wet conditions forming peats, or Histosols (ST and WRB). Histosols typically have layers containing more than 20% soil organic carbon that together are at least 40 cm thick in the first meter below ground surface. While the majority of Histosols are located in cool climates, they also occur in tropical swamp forests and papyrus wetlands. The Cuvette Centrale depression in the Congo Basin is one of the world's most extensive swamp forests with Histosols (Dargie et al., 2017). Other major areas with Histosols are in Kalimantan and Sumatra in Indonesia and in the Amazon basin (Miettinen et al., 2016; Xu et al., 2018).

In subhumid tropical climates, annual precipitation is equal to, or less than, the reference evapotranspiration (ET₀), but still greater than half the ET₀ (0.5 < AHI ≤ 1). In this zone a pronounced dry season occurs around the winter solstice (ustic soil moisture regime in ST). Weathering and leaching of minerals are less intense compared with the (hyper)humid climates. Less rainfall leads to some upward capillary movement of solutes during the dry period when evapotranspiration exceeds precipitation. Moreover, the soils are often enriched with airborne particles as desert dust can be transported over long distances, such as by the Harmattan winds in West Africa, which frequently obscure the sunlight during daytime. Processes of desiccation play an important role: when soils dry out, completely hydrated forms of iron and aluminum hydroxides may lose at least part of their crystal water. Goethite (α-FeOOH) is transformed into hematite (α-Fe₂O₃), following the reaction

Fig. 2 Soils of humid tropical climates: (A) a Xanthic Haplustox (ST) or Xanthic Ferralsol (WRB) on the Makonde plateau, Tanzania. The yellowish color is due to goethite. (B) a giant Spodosol (ST) or Podzol (WRB) in Malaysia. The white sand in the upper part has been leached under which iron-humus complexes have accumulated. If the iron-humus enriched horizon occurs at more than 2-m depth, the soil will be a Spodic Quartzipsamment (ST) or Albic Arenosol (Bathypodic) in the WRB. Photographs: (A) Stefaan Dondeyne, (B) ISRIC.

The dehydration of goethite and the formation of hematite, are responsible for the striking difference in colors between soils formed in humid tropical climates and those of the subhumid zones. In humid tropical climates soils are dominantly yellow or yellowish-brown (the color of goethite) (Fig. 2A), whereas they are predominantly red when they form in subhumid climates due to the presence of hematite (Fig. 3A).

Because of the less intense weathering and leaching, and the addition of dust, soils of the subhumid tropical zone are less acidic and have higher base saturation than their counterparts under humid climates. Typical soils are Kandiuustalfs (ST) or Lixisols (Fig. 3B) and Nitisols (*pro parte*) (WRB), together with Paleustalfs and Haplustalfs (ST) or Luvisols (WRB). Oxisols (ST) or Ferralsols (WRB) often occur here too, they probably formed under past more humid climates. In flat areas, where heavy rainfall alternates with pronounced dry seasons, seasonal stagnation of surface water occurs over large areas, leading to the formation of Albaqualfs (ST) or Planosols (WRB) (Fig. 3B). Where soils have developed from basic rocks (such as basalts, or limestone) and where there is a pronounced dry season they result in the formation of shrink-swell clays, (montmorillonite) Vertisols (ST and WRB).

Soils in semi-arid and arid climates

In semi-arid and arid climates annual precipitation is equal to, or lower than, $ET_0/2$ ($AHI \leq 0.5$). When the soil is moist, water will dissolve soluble minerals. When evapotranspiration exceeds precipitation, water will move upwards and the soluble minerals will precipitate. This process leads to the enrichment of the soil with secondary calcium carbonate ($CaCO_3$), gypsum ($CaSO_4 \cdot 2H_2O$), and in the most dry climates soluble salts such as mirabilite ($Na_2SO_4 \cdot 10H_2O$), thenardite (Na_2SO_4), hexahydrite ($MgSO_4 \cdot 6H_2O$), nahcolite ($NaHCO_3$), soda ($Na_2CO_3 \cdot 10H_2O$), trona ($Na_3CO_3HCO_3 \cdot 2H_2O$), and halite ($NaCl$). The accumulation of soluble salts is known as 'salinization.'

Soils of sand dunes, which are conspicuous landforms of semi-arid and arid climates, are classified as Torripsamments (ST) or Arenosols (WRB). Other soils do not show much development either, apart from the accumulation of carbonates, gypsum, or salts. Following Soil Taxonomy these soils are Aridisols in particular Calcids (ST) or Calcisols (WRB), Gypsisols (ST) or Gypsisols, and Durids (ST) or Durisols (WRB). Other common soils include Natrustalfs (ST) and Solonetz (WRB), both of which have a high sodium content in the subsoil. Where salts have accumulated at the soil surface Salids (ST) or Solonchaks (WRB) are found. Where

Fig. 3 Soils of subhumid climates: (A) Kandiusalf (ST) or Lixic Nitisol (WRB) from Tasmania, Australia. The reddish color indicates the dominance of hematite, the formation of which requires dry seasons. (B) An Albaqualf (ST) or Solodic Planosol (WRB) from Victoria, Australia. The whitish color in the upper 40 cm illustrates the seasonal stagnation of water. Photographs: Stefaan Dondeyne.

cold ocean currents meet desert shores, such as the Benguela current along the west coast of southern Africa, mist drifts inland, carrying moisture and solutes from the sea. This gives rise to the deposition of sulfates. In this area, up to 150 km inland, the vast areas of accumulated gypsum can be attributed to the influence of mist.

Because of the scarcity, or total lack of vegetation, wind plays a large role in these climates and has a considerable impact on the soils. Wind contributes to the speed of evaporation, but also removes fine particles (as dust storms), and also leads to the formation of dunes. Where fine particles are removed, a gravelly surface is often left behind, known as a desert pavement (Fig. 4A). The gravel stones at the surface are shaped by scouring sand particles creating 'ventifacts' and can develop a shiny surface, the 'desert varnish' (Fig. 4B).

Soils in warm temperate climates

At mid-latitudes, the seasonal variation of the sun's position results in summer and winter seasons. In maritime regions, such as in western Europe, the influence of warm oceanic currents contributes to the occurrence of mild winters. In continental locations, such as in Ukraine, southern Russia or the Midwest of the USA, climate is much drier leading toward semi-arid. Summers are hot, but winters are also much colder than in the maritime regions (mesic to thermic in ST). In most of the temperate zone, precipitation is evenly distributed over the year but dry summers alternate with wet winters around the Mediterranean Sea. This climate corresponds to the xeric soil moisture regime (ST) that also occurs, e.g., in California (USA), South Africa and southern Australia.

Under warm humid temperate climates excess precipitation gives rise to chemical weathering and leaching. With the large fluctuation in temperature and varying rainfall patterns, rates of chemical weathering are also variable. However, the net transport of substances, either in solution or as colloids, from the upper parts of the soils to the lower parts or to the groundwater is the common denominator for most of the soils in warm temperate climates.

Chemical weathering of non-calcareous parent materials leads to the release of free iron hydroxides (amorphous iron hydroxide, $\text{Fe}(\text{OH})_3$; goethite, $\alpha\text{-FeOOH}$) and the formation of clay, particularly illite. Clay formation mainly results from the weathering of muscovite, accompanied by the partial or total loss of K^+ ions. Chemical weathering of calcareous parent materials starts with the dissolution and removal of carbonates. It is only after decalcification that other processes, such as 'brunification' start. This process involves the release of free iron hydroxides that give the soils in warm temperate climates their characteristic yellowish-brown color. In warm temperate climates with distinct dry summers, dehydration of the hydroxides leads to more red colors (rubefaction) due to the formation of hematite ($\alpha\text{-Fe}_2\text{O}_3$) (Fig. 5A).

Fig. 4 Soil features of arid climate: (A) A Natric Argicryid (ST) or a Salic Solonetz (WRB) with a desert pavement in the Gobi desert (Mongolia). The white streaks are accumulations of lime and salts. (B) A stone that has been shaped by wind abrasion (ventifact). The shiny surface is the so called desert varnish (Gobi desert, Mongolia). Photographs: Stefaan Dondeyne.

Fig. 5 Soils of temperate warm climates: (A) A Calcic Haplustalf (ST) or Luvic Calcisol (WRB). Under the brownish plough layer (0–30 cm), a reddish clay enrichment horizon occurs (30–65 cm). Manganese concretions together with part of the parent material (Andesite) is still found as a gravel layer (65–80 cm), below which a hardpan of calcium carbonate is formed (South Africa). (B) Lamellic Hapludalf (ST), or an Albic Luvisol (WRB). Directly under the humus rich surface horizon (0–10 cm) first there is a bleached eluvial horizon (10–25 cm), followed by a brownish clay enrichment horizon (25–70 cm). Below this horizon, more clay eluviation and illuviation occur in bands (70–125 cm) (Poland). Photographs: Stefaan Dondeyne.

Fig. 6 Soils of temperate cool climates: (A) A Pachic Calciustoll (ST) or Calcic Chernozem (Poland). Due to the cool climate organic matter decomposes only slowly and accumulates in the surface horizon. (B) Typical Calciustept (ST) or Cambic Calcisol (WRB) (Romania). Soil development is limited to the development of a cambic horizon (40–60 cm). Due to the dry climate calcium carbonate precipitates along cracks and soil structural elements which appear as white concretions. Photographs: Stefaan Dondeyne.

The physical translocation of clay particles by gravity water from the upper soil horizons to the lower soil horizons is called clay illuviation. It results in clay-enriched, subsurface horizons, known as argillic (ST) or argic (WRB) horizons (Fig. 5B). The process is enhanced by a soil environment with relatively small content of exchangeable Ca^{2+} and Al^{3+} ions, both of which tend to flocculate the clay particles, thus inhibiting the dispersion necessary for clay translocation. Furthermore, it is favored by desiccation of the soil through which larger pores and cracks are created, and by the occurrence of heavy rain showers, creating the low-electrolyte environment needed for clay translocation.

In warm humid temperate climates Alfisols (ST) or Luvisols (WRB) are typically the dominant soils (Fig. 5). In drier climates, soils with accumulations of calcium carbonate occur (Fig. 6). Toward the boundary with cool and drier temperate climates, organic matter builds up in the surface horizons where Mollisols (ST) or Chernozems (WRB) are encountered.

Soils in cold temperate climates

The mean soil temperature of cold temperate climates (mostly, frigid and cryic in ST) is above freezing point, but is less than 8°C , therefore, no permafrost occurs here. However, at higher elevation as, for example, on the Tibetan plateau, there are areas where permafrost occurs. Large parts of this climatic zone have been formerly glaciated. This has resulted in the deposition of glacial and periglacial deposits such as boulder clays, outwash materials, fluvial deposits of braided river systems, lake sediments, loess, and cover sands. The heterogeneity of these sediments, together with the conditions of cool temperate climates, results in a variety of soil-forming processes.

Of importance in the cold temperate climates are the long, cold winters, during which the soils are frozen and covered by snow. In areas with slowly permeable parent materials (boulder clays, lake sediments, etc.) meltwater stagnates during springtime, causing waterlogging and temporary reducing conditions. This gives rise to dissolution and removal of iron, decline in soil structure in the surface horizons, and acidification. On better-drained parent materials (cover sands, braided river deposits, etc.), water stagnation may still be present due to the frozen subsoil, but not for as long and not as severe as on poorly drained parent materials. Under coniferous forest, acidic soils develop. On sandy deposits, the process of cheluviation takes place, whereby organic acids, released from the vegetation debris, complexed with aluminum and iron are subsequently leached downwards and deposited in the lower

Fig. 7 Soils of the cold temperate climates: (A) Typical Haplocryods (ST) or an Albic Rustic Podzol from Latvia. Acidification of the soil, due to the humid climate and enhanced by coniferous forest, activates the leaching of complexes of iron and aluminium resulting in a white, bleached horizon (30–50 cm) and subsequent deposition to form a reddish horizon (50–80 cm) (Latvia); (B) Typical Haplocryoll (ST) or an Haplic Kastanozem from Mongolia. The upper 40 cm is rich in organic matter, and the dominant brown color is typical of soils of the drier climate under short steppe vegetation. Photographs: (A) Stefaan Dondeyne; (B) Stephan Mantel.

parts of the profile. This results in the development of Spodosols (ST) or Podzols (WRB) (Fig. 7A). The low temperature also hampers biological activity in these soils, consequently, humification and bioturbation are slow.

During the warm summers soil life becomes active and contributes to the process of homogenization of soil material. Where summers are sufficiently long and warm, and winters not very severe, biological activity in the soils contributes greatly to the processes of homogenization and humification. This is especially so under grasslands with a large amount of organic matter. Burrowing soil animals homogenize the soils to a considerable depth, sometimes up to 2 m, and thoroughly mix the organic matter with the mineral soil constituents, which is called bioturbation.

Soils in sub-arctic and arctic zones

In the sub-arctic or boreal zone, the average temperature is above 10 °C for one to at most 3 months; in the Arctic zone, it is even colder. Maritime regions may be hyper-humid to humid ($AHI > 1$), for example, Iceland and northern Norway, whereas, continental regions may be semi-arid to arid ($AHI \leq 0.5$) as in central Yakutia in Russia. Weathering under the low temperatures in the subarctic and Arctic zones is almost exclusively physical; chemical weathering is limited and, if any, it is restricted to the short periods of thawing. In addition, biological activity is low due to the low temperatures.

The effects of freezing and thawing are characteristic for the soils in sub-arctic and Arctic climates and, in many cases, there is permafrost (permanently frozen subsoil with ice segregation). The annual freezing and thawing of the soils result in thermal contraction and expansion of water and minerals in rocks, which slowly weaken the rock structure and permits water to enter in cracks. The freezing of water further widens the cracks, as ice has a lower bulk density (hence more volume per weight) than water (0.9 versus 1.0 kg dm^{-3}), and over time the rock will disintegrate into angular fragments. The annual freezing and thawing results in the process of ‘cryoturbation,’ giving rise to features such as horizon involution (Fig. 8), frost heave, cryogenic sorting, and patterned grounds (e.g. stone polygons).

In permafrost areas, soils are dominantly Gelisols (ST) or Cryosols (WRB). These soils have, by definition, permafrost occurring within 100-cm depth, or within 200-cm depth in association with gelic materials above it. Alternatively, they have one or more cryic horizons within 100 cm of the soil’s surface.

Fig. 8 Soils of sub-arctic climates: (A) Active cryoturbation pulls organic rich material from the surface downwards in a wedge shape pattern when thermokarst mounds are formed (central Yakutia, Russia); (B) a similar wedge shape pattern in a sandy soil in northern Belgium, where it is obviously a relict feature. Photographs: Stefaan Dondeyne.

The low rate of humification of organic matter and the wet conditions during the thawing periods result in the accumulation of peat at the surface. Peat soils are among the most widespread soils in the (sub)arctic regions. Approximately half of the Earth's peat soils, i.e. Histosols (ST and WRB), occur in the circumpolar region of the northern hemisphere.

Soils in changing climates

The ever-increasing net emission of greenhouse gases is resulting in an unprecedented global warming of the climate (IPCC, 2021). A comprehensive assessment of the potential impact of climate change on soils, and of all the feedback loops that can be expected between climate and soil processes, is beyond the scope of this contribution. However, based on the insights into the relations between climate and soil formation some critical points can be highlighted. When soils under permafrost are included, the soil organic carbon content is estimated to be 3200–4100 Gt C, which is approximately seven times as much as that stored in the above-ground biomass (450–650 Gt) and about four times that in the atmosphere (860 Gt C) (Friedlingstein et al., 2020).

Soils have an enormous potential for carbon sequestration where organic matter can accumulate, as in soils under permafrost (Gelisol ST, or Cryosols WRB), in peatlands (Histosols), and in soils typical of grasslands (Mollisols in ST, or Chernozems and Kastanozems in WRB). Recent research has also highlighted historical losses from the soil organic carbon pool, and pointed to the added risk of future accelerated losses under a warming climate (Bossio et al., 2020). The Arctic permafrost, which stores roughly 1700 Gt C, is of great concern. Rapid thawing and thermokarst processes might release significant amounts of carbon into the atmosphere in a few days or years. While carbon dioxide emissions in the Arctic are proportionally higher than other greenhouse gases, methane emissions are expected to rise as anoxic conditions in thawing permafrost and soils increase (Miner et al., 2022). Inhabitants of sub-arctic and Arctic regions are already confronted with the consequences of global warming because the warming is especially intensive in permafrost areas. In central Yakutia, the thawing of arable land leads to the formation of new thermokarst mounds (Fig. 8A). In the process, Gelisols (ST) or Cryosols (WRB) are transformed in soils with seasonally stagnating water (Aquic Haplogelols, in ST, or Stagnic Cambisols, WRB) or become salt affected soils (Natric Argiorthels in ST, Calcic Solonetz in WRB). These rapid changes in the soil render much of the former arable land unusable for agriculture (Desyatkin et al., 2021).

The increase in temperature will also lead to greater evapotranspiration and higher rates of both geochemical and biochemical processes. For example, soil N (nitrogen) cycling will shift from microbial immobilization to enhanced mineralization, nitrification and denitrification across global terrestrial ecosystems (Dai et al., 2020). Therefore, whereas soil carbon sequestration is recognized as a way to reduce atmospheric carbon dioxide, climate warming may also hasten loss of the soil's carbon stock. It has been demonstrated that soil carbon in particulate organic matter and in mineral-associated organic matter has different vulnerabilities to climate change. In Europe, soils under arable land and coniferous forest contain the largest but also the most vulnerable carbon stocks (Lugato et al., 2021). Given the complex interactions between all these processes, it remains important to appreciate the different processes of soil formation. Research in California, for example, showed that while forests are frequently thought to be important for carbon sequestration, they may be in peril where extreme heatwaves, drought, and wildfires become more common. In such conditions, grasslands – that typically occur on Mollisols (ST), or Chernozems and Kastanozems (WRB) – are more resilient to climate change and serve as important belowground carbon sinks (Dass et al., 2018).

Soil forming processes such as cryoturbation, rubefaction and ferralitization only occur under very specific climatic conditions. Other processes such as brunification, decalcification, clay illuviation, and cheluviation occur under a wider range of climatic conditions. Some soil properties may persist after changes in the climate, while others, such high salt content or secondary calcium carbonates, can quickly be removed when climate becomes more humid. Persistent soil properties can be good indicators of past climatic changes. The relict wedge shape pattern in the sandy profile of northern Belgium (Fig. 8B), illustrates that at the end of the last glaciation similar processes of thermokarst must have occurred which are now active in sub-arctic regions (Fig. 8A) as described by Desyatkin et al. (2021).

Frost action in periglacial conditions also result in the formation of ice plates and wedges following polygonal structures. Water stagnation in the layers above the permafrost leads to formation of a bleached horizon. This white (albic) material will seep into the cracks left by ice plates and wedges after thawing. Such a reticular pattern of white tongues (albeluvic glossae), is the most plausible process leading to the formation of Glossudalfs (ST) or Retisols (WRB) (Dondeyne and Deckers, 2019; van Vliet and Langohr, 1981). The presence of these soils in current warm temperate climates is a testimony of the cold climatic conditions that prevailed during the last glaciation (Fig. 9A).

Rubefaction, the process of red coloring as a result of the formation of hematite, is associated with subhumid climates that have a long, hot dry season. The occurrence of such soils in warm temperate climates (Fig. 9B) is attributed to subhumid warm climates during the Mesozoic Era.

Fig. 9 Soils in changing climates: (A) Glossaqualf (ST) or Retic Stagnosol (WRB) in Belgium. Note the white tongues (albeluvic glossae) that extend from the white eluviation horizon (40–60 cm) and cut across the brownish clay-enrichment horizon. These white tongues follow a polygonal pattern and are remnants of periglacial processes of the last glaciation. (B) The strong reddish colors of this Hapludult / Haplic Alisol under a coniferous forest in Luxembourg shows that the parent material has been weathered in a tropical subhumid climate. Photographs: Stefaan Dondeyne.

Conclusions

Soils bear a strong stamp of both present and past climates, consequently early soil classification systems integrated climatic characteristics explicitly. Though modern international classification systems are based on observable or measurable soil properties as these classification systems rely on concepts of soil formation, major classification units inevitably correspond to variations in climate. Temperature is a key climatic factor because it not only regulates the speed of weathering: higher temperatures lead to faster chemical processes, but also more biological activity which plays a crucial role in the breakdown or the accumulation of organic matter. Furthermore, temperature, together with wind, are also key to the rate of evapotranspiration. The ratio between precipitation and evapotranspiration determines whether soil water fluxes are predominantly downwards or upwards. Downward fluxes result in weathering and eluviation of soluble minerals and colloids. Where strong evapotranspiration occurs, soluble minerals as carbonates, gypsum and salts are redistributed in the soil and accumulate at or near the surface. Raising temperature and changing precipitation patterns will strongly affect all of these soil processes.

Abstract

In terrestrial environments, soils are the primary boundary between geology and biology. Not only do biological influences in soils change with depth, they change with temperature, latitude, water availability, and human influence. The huge number of different organic compounds in the soil dwarfs the variety of minerals present and can be very difficult to identify. When considering the influence of biology on soil development on a large scale, we tend to think in trends and abundances of the various organic influences rather than specific intricacies of particular ecosystems. By separating soil systems by biological zones, we can understand better all of the variation in biological influences and development in soils across different latitudes and landscapes.

Key points

- Soil biology has a large influence on soil development
- Biological influences vary with depth in all soils
- Soil biological communities vary with variations in other soil forming factors
- Variations in soil biology affect rates of soil decomposition, nutrient cycling, and carbon storage

Nomenclature

% Carbon	Carbon content (grams of carbon per 100 g of soil)
% Clay	Clay content (total number of particles per 100 particles that are below 2 μm in size)
% Nitrogen	Nitrogen content (grams of nitrogen per 100 g of soil)
C:N	Carbon to nitrogen ratio (unitless value)
Epipedon	Diagnostic surface horizons of soils, often based on organic matter content and base saturation
pH	negative log of hydrogen ions (unitless)

Introduction

In terrestrial environments, soil is the direct interface between geology and biology. Biology has varying influences on soil properties with depth resulting in a notable transition of biological activity from top to bottom along horizon boundaries. To understand the myriad of biological components in a soil and how they affect soil development, it requires a fairly large net to be cast, which would include everything from microbes and fungi, to invertebrate detritivores, herbivores, and carnivores, vertebrate species, and, of course, the plants and their root systems. The abundance and influence of each of these groups varies along climatic boundaries in terrestrial environments and provides the foundation for the changes in ecosystems we see along these boundaries.

Components of soil organic matter

Soil organic material (SOM) is made up of an incredibly wide range of compounds originating from biological contributions both in and above the soil. The amount of variation in organic carbon and nitrogen based compounds in soils is striking compared to that of the mineralogy of the soil parent material. The dominant source of the biomass contribution to the soil in most ecosystems is from terrestrial plants, although biomass from microorganisms and animals cannot be discounted. Plants shed leaves, branches, roots, propagate pollen, root exudates, and respire from the root systems, and these contributed parts are consumed by decomposers or herbivores. The consumed material is transformed into various excrements from those species, and then other decomposers break down that material even further and into increasingly recalcitrant compounds. The rate at which this occurs is strongly related to the temperature and moisture levels in the soil environment which results in the establishment of particular suites of soil organisms.

The quality of the organic material also plays a substantial role in soil development. This decomposition is primarily mediated by the microbial community. Decomposers in the soil preferentially consume detritus with a low carbon to nitrogen ratio. This suggests that the amount of nitrogen, one of the key macronutrients in the soil, is in sufficient amounts to fuel the metabolic activity. Carbon to nitrogen (C:N) ratios provide a fairly ubiquitous and cursory assessment of soil quality as it is a predictor of rates of biological activity in the soil itself. Organic compounds that contain a relatively large carbon to nitrogen ratio are considered to be of lower quality and do not decompose nearly as fast. As decomposition of organic compounds continues, increasing amounts of nitrogen are used in metabolic systems from the material, which increases the carbon to nitrogen ratio. This older organic material becomes increasingly recalcitrant, more stable, and tends to remain in the soil for much longer periods of time (Swangjang, 2015). For example, grasslands typically accumulate organic material with a lower C:N ratio while coniferous systems generate organic material that usually has a high C:N ratio. A mixed forested environment or typical hardwood system would fall between these two end members in their C:N ratios. In Table 1, a list of average carbon/nitrogen ratios are included for dominant ecosystems. Deciduous forests generally have higher ratios than evergreen forests and drier landscapes.

Organic matter in soils can be found in several different forms, all of which can exist at the same time in various stages of decomposition. Surface plant residue resides on the surface of the soil and contains leaf litter, grass, crop or pasture material. Buried plant residue is contained within the soil and contains plant material that is greater than 2 mm in size. Particulate plant material consists of partially decomposed material that is smaller than 2 mm. All of the above portions of organic matter are considered labile in that they will decompose in the order of days to years, based on other environmental factors where they are deposited. Organic matter that lacks an organic structure and can be determined to be specifically derived from plant or animal is characterized as humus. These fractions of organic matter are usually associated with soil aggregates and are smaller than 1 mm, and are considered to be more stable. This reflects their more advanced state of decomposition and in part the physical and chemical protection from non-organic compounds in the aggregate structures. They can remain stable in the soil from years to decades. Charcoal, charred material, and ash from fire related processes create resistant organic carbon (ROC), which will remain stable in the soil from decades to thousands of years (Stockmann et al., 2013).

Soil ecosystems

Some aspects of soil biology do not change a great deal from ecosystem to ecosystem. For example, the nitrogen cycle is controlled by the microbial biomass in all systems. A relatively large number of plants establish relationships with mycorrhizal fungi in most ecosystems and utilize these relationships to channel nutrients to the rhizosphere, which has a unique set of conditions than the areas of soil further from the root zones. Soil animals in most ecosystems around the world are dominated by arthropods (mostly

Barren or sparse vegetation	26.8

Data after Wang et al., 2010 based on modelling from Glopnet datasets for each biome listed.

mites and springtails) and nematodes, although relative proportions of those two phyla can shift when considering grassland compared with forest soils, for example. However, the relative abundances of all these species, the rate at which they perform their roles in transforming soil physical and chemical properties, and the way they operate can change as the other influences of soil development change. With the differing chemical compounds and structures in plant biomass from ecosystem to ecosystem, it is logical to expect plants would contribute organic material to soil in different ways and in varying amounts. It is therefore necessary to organize the discussion of this wide variation of biological influences in a way that can be more easily evaluated. One way to do this is to discuss the differences in soil biological activities in various ecosystems. Here, I have organized the soils into the common climatic zones and in the general order of moving from the tropical environments at the equator, through the grasslands and deserts of the lower latitudes, through the temperate forests and into to the boreal forest and tundra ecosystems. This does not imply that all soils in a climate belt are equivalent in nature with regard to their biology. Biology is but one of five soil forming factors, variation in the other factors (climate, topography, parent material, and the age of the soil) can have a marked effect on the soil biological components as can the variation in microclimate across a landscape. With the overwhelming number of species present in soil communities, it is impossible to discuss with any degree of certainty the precise proportions of soil organisms on an ecosystem scale. However, in recent years there have been enough data to identify generalized patterns of species distributions and the SOM that they are associated with on a large scale. Interestingly, while the amount of above-ground biomass is highest at the latitudes nearest to the equator, the largest amount of soil biomass is located in the high latitudes of the northern hemisphere associated with boreal and tundra ecosystems. However, the amounts of below ground microbial biomass remain fairly consistent through all the lower and mid latitudes and it increases substantially only in the high latitudes (Crowther et al., 2019).

The amount of organic carbon and nitrogen stored in ecosystems per unit area is dominated by wet and or cold areas (wetlands, boreal forests, and tundra) (Fig. 1). While the amount of microbially associated carbon and nitrogen in ecosystems with large organic matter content is also large, the total amount of microbial biomass does not vary equally and in proportion as organic matter varies. Microbial biomass can be somewhat limited by saturated conditions, therefore, the wetland microbial population is less than that of the tundra. When considering the amount of microbial biomass as a function of depth and amount of land covered by the tundra ecosystem, a different pattern emerges. Boreal forests, due to the amount of land, depth of the soil, and large organic matter accumulation, have the largest amount of microbially associated biomass at depth, followed by mixed forests, tropical and

Fig. 1 Average carbon and nitrogen concentrations of soil organic material and microbial biomass in various ecosystems. Graph of data published in Xu et al., (2013).

Fig. 2 Average microbial biomass in various biomes as a function of depth. Graph of data published in Xu et al. (2013).

subtropical forests, and grasslands (Fig. 2). Wetlands and tundra display a smaller overall share of the world's microbial biomass because of the smaller amount of land covered by wetlands and the shallower soil depth of soil in the tundra.

In addition, the discussion of soil biology in this chapter will exclude agricultural systems, which can be present in nearly all the natural ecosystems described below. With the wide variation in types of crops grown, amendments added to the soils, and human driven alterations of other physical and chemical properties on farmland, it can be difficult to consider soil biology in this context with any degree of accuracy. A great deal of research has gone into the structure and behavior of soil organisms under various forms of agriculture in most regions of the world (Bünemann et al., 2006; Bender et al., 2016; Hendrix et al., 2020). It is relatively common that the original soil community will remain intact for several years after a landscape is converted to agriculture. But over time, the below ground community will adjust and begin to reflect ecosystems more similar to those related to the crop being grown.

Tropical soil systems

The rate of decomposition in tropical soils is the fastest of all the ecosystems. This is primarily due to higher soil temperatures which increase biological activity and metabolic rates, and the lack of seasonality in plant growth (Krishna and Mohan, 2017). The soil community overall, despite their overall tendency to work intensively and fast at their various ecosystem functioning roles, is highly sensitive to changes in moisture and temperature. The community itself does not develop in such a way that it can deal with diverse survival strategies for harsh environments and is thus subject to major disruptions caused by drought, unexpected cold conditions, or fire events, for example.

This region is noted for incredibly high biological productivity on the surface and, in many cases, deep and highly weathered soils. While there is a great deal of organic matter in the soils of the tropics, these soils tend to have small amounts of biologically labile fractions, a smaller microbial biomass, but a very large fraction of organic material associated with clay minerals. The humus organic carbon fraction dominates, in part due to the high rate of clay formation related to chemical weathering activities. This keeps the SOM stable for long periods of time and results in the carbon being buried deep in the soils. This will, over time, develop into humin–mineral complexes with organic materials being bound in some way to inorganic material. Complexed material in soil is not exclusive to tropical zones, but is a common characteristic of the deeper horizons. This complexed material can help to hold soil water and supply deeper rooting systems with nutrients for longer periods of time and prevent increasing compaction from the weight of the thick soil above, which will allow microorganisms to function more easily (Bruun et al., 2010).

There can be considerable variability in soil communities across the tropical landscape depending on smaller scale variations of other soil forming factors. Environments that are poorly drained, for example, can result in peat systems, such as those in Indonesia. These high moisture and high productivity situations will result in histic epipedons with organic horizons extending beyond several meters in depth. In contrast, those areas along slopes with nutrient poor parent material can have very small amounts of organic materials and a very different above- and below-ground communities from those of the surrounding areas.

Savanna and grassland soil systems

The amount of organic matter contributed to the soil by grasses is greater than that of the deciduous forest environments because grasses contribute the majority of their biomass to the soil at the end of each growing season. In a typical grassland, there is a relatively equal distribution of biomass above- and below-ground in the soil from the grasses. When grasses die, they contribute all of their biomass either on or below the surface which contributes to the SOM of the soil system throughout the epipedon and into some of the subsurface horizons.

The greater proportion of woody material derived from either shrubs or trees in savannas makes the structure of their soil ecosystem somewhat different, especially in the warmer areas of the Earth. The A horizon is typically more nutrient poor than at higher latitude because of higher rates of decomposition and more litter with a large carbon to nitrogen ratio. In addition, some of these areas are dominated by ants and termites in the soil macrofauna rather than earthworms and springtails which are frequently more dominant in other biomes.

In traditional grasslands of the more temperate zones that have much less woody plant material, organic material is more concentrated in the first meter of soil due to the volume of biomass turned over annually by the grasses and their root systems. The leachate in these areas commonly has a higher pH than in the savannas, and the organic matter itself has a lower carbon to nitrogen ratio which encourages decomposition. The resulting epipedon is fairly soft and dark with a high base saturation.

Desert soil systems

The amount of biological activity and biomass in desert soils is lower than that of other ecosystems, as one would expect. The growth rate above the surface is slow due to the lack of water, which reduces the amount of food source available for the living biology below ground. The density of root systems is usually low because large gaps exist between plants that are competing for these limited resources. The frequency of naturally formed Entisols (Soil Survey Staff, 2014), which lack a B horizon, is much greater in these areas with the slow rate of soil development because weathering processes do not progress as rapidly and biological contributions are few. Compared with all the other ecosystem types, however, treating deserts as a single entity can be problematic because they can exist from the tropics to the poles; they are defined simply by a lack of precipitation rather than temperature. These different latitudinal locations can have a marked effect on the communities of soil dwelling fauna and flora and contradict what would be considered a standard description. For example, the strongly alkaline nature of hot desert soils and high salinity of hot desert basins would contrast markedly with the acidic nature of the non-calcareous polar deserts, and which would affect the soil dwelling biota. The incredibly short growing season in the polar deserts is also a severe restriction to above ground plant growth allowing the soils to develop in the near absence of root systems. What can be said, however, is that most deserts force biological communities to employ survival strategies for such extremes compared to the other soil ecosystems.

Although some parts of a desert landscape may appear barren at a glance, deserts can have quite active and resilient biocrusts on the surface. These crusts are created predominantly from microbial matter and take advantage of the unshaded and untrampled regions of the deserts to form a living surface across wide expanses. These communities of cyanobacteria, mosses, and lichen are usually the pioneering species in any newly exposed environments prior to soil formation. In the arid and semi-arid areas, however, they can form crusts of several millimeters in thickness on the surface and will serve to alter or enhance nutrient cycling, regulate the soil water balance and thermal energy balance of the soil system below (Bowker et al., 2018). These biocrusts will attach themselves to the surface substrate and slow erosion and, subsequently, the loss of epipedon material that the rest of the soil biological system relies on. The overall slow development of biological systems in water depleted regions is especially important to note when discussing these biocrusts and their propagation as new crusts in disturbed areas can take several hundreds to several thousands of years to re-establish themselves and return to their full previous function.

Subtropical and temperate systems

Deciduous forest systems

Deciduous ecosystems are dominant in the subtropical to temperate latitudes. Some of the soils of these ecosystems are exposed to frost during part of the year or to heavily frozen ground, therefore, the diversity and general composition of the various suites of organisms can change a great deal with latitude and elevation. In these deciduous environments, trends in soil activity occur in predictable annual pulses as the seasons change. As the leaves drop from the trees in the autumn, considerable organic material is added to the litter material on the soil surface. Decomposition of the litter can start and continue over winter, but the rate depends markedly on temperature. Large rates of decomposition in and on the soil typically do not start until spring.

Both macrofauna and bacteria are a dominant force in the decomposition of the leaf material, but fungal presence is also very high because of difficulty in the decomposition of lignin in woody material by other organisms. In deciduous forests, the fungal to bacterial ratio is usually between 5:1 and 10:1. Deciduous tree species can form relationships with either endomycorrhizae or ectomycorrhizae, which will result in an expansive network of filaments through the soil profile. This symbiotic relationship results in large rates of nutrient cycling and carbon mineralization.

Deciduous soils tend to have less organic matter in the A horizons compared with grassland systems due to the high turnover of grasses which incorporates more organic material to the system on an annual basis. However, the increase in clay content from enhanced chemical weathering processes in wetter environments in these forested soils leads to increased aggregation and physical and chemical protection of the SOM. This, combined with the greater rooting depth of the vegetation, will result in larger amounts of SOM throughout the profile than in grasslands. In addition, the presence of anecic earthworms, the deeper roots of trees and other animals that make vertical burrows cause organic material to be distributed deeper into the soil than in non-forested regions.

Coniferous forest systems

Coniferous systems contribute more plant tissue to the soil annually than any of the other ecosystem. However, the material is of very poor quality (high carbon to nitrogen ratios). This results in thick layers of dominantly fibrous detritus in the uppermost O horizon with much less organic material contributed to the A horizon than in deciduous forests. Despite this contribution, the organic matter that is incorporated is much more stable and more difficult to break down due to mineral associations and the formation of complexed compounds, which result in more organic material at depth as the soils develop. In addition, the average rooting area of conifers is wider than that of deciduous trees, contributing organic carbon in a larger perimeter in the soil from root shedding, exudates and other associations in the rhizosphere.

The overall acidic nature of coniferous systems tends to reduce the diversity of soil biological systems. This is primarily related to the pH of the surface plant residues which are deposited throughout the year. The reduced diversity is especially true of the macroinvertebrate detritivores, whose abundance declines precipitously during the transition from deciduous to coniferous forest. Earthworm density in coniferous forests is in the order of 10 times less than in deciduous forests due to the often low pH of the litter contributed to the soil there. The fungal to bacterial ratio is much higher; these can be in the order of 100:1 or 1000:1 depending on other soil forming factors (Korboulewsky et al., 2016).

A comparison of coniferous and deciduous soil systems from the piedmont of the south eastern USA with similar bedrock (gneiss) reveals some distinct differences in soils that are less than 600 m apart (Fig. 3). The acidic nature of the organic material incorporated from conifers causes the pH of the soil to decrease, which enhances the rates of chemical weathering. The formation of clay minerals from many silicate minerals by hydrolysis will produce siliceous acid, which further decreases the pH of the soils here. If the primary minerals in the soils contain metals, such as iron, this results in a much more oxidized soil with higher clay content than the soil forming below the deciduous forest.

Boreal forest systems

The suite of organisms in the boreal forest soils is often less diverse than that of the lower latitudes because of the need for the organisms to survive long periods of hard freezing and months of little to no activity in the soil. In the absence of permafrost, soil temperatures can stay at or above freezing below a few centimeters depth, which allows species to survive in the uppermost horizons. The hard freeze in the winter month causes dormancy of the organisms and most activity slows to a halt. However, in the spring during the thaw, this ecosystem can have a wide range of biological activity depending on local drainage systems in the area. The immense amount of snow melt and waterlogged areas can essentially turn forested lands to wetlands for portions of the year, which will result in pulses of biological activity from different types of organisms.

With slow rates of evaporation and perpetual shade from the evergreen species in the region, the soil can retain a great deal of moisture allowing thick beds of sphagnum moss to develop above the soil surface. Decomposition of the dead moss below is slow due to the low temperatures and high moisture content in the soil pores which encourages the rapid accumulation of organic material in the soil. As discussed above in the coniferous forest section, the high acid content and constant shedding of conifer

Fig. 3 Comparison of a soil from a coniferous ecosystem and deciduous ecosystem in Redlair, NC. The coniferous soil (A) has a lower pH and higher clay content than the deciduous soil (B). Despite these soils being located merely several hundred feet apart, the influence from the different plant and ecosystem contributions plays a role in altering both physical and chemical properties. needles contribute more biomass to the soil than any other ecosystem type allowing this boreal soil biome to store more organic carbon than all of the other soil types combined. This has had a marked impact on the overall ability for soils to sequester carbon from the atmosphere.

Bogs are another common feature of boreal lands that can result in a slightly different biome from that of the forested counterpart. As the glacial lakes in these regions slowly fill with sediment and organic detritus, the resulting peat bogs become large, treeless carbon sinks with a layer of sphagnum moss and other unique plants on the top. The anoxic layers of this soil lie just below the surface and are dominated by a community of bacteria that are both resistant to disturbance and slow working (Allison and Treseder, 2011). Nutrient cycling in these soils, as a result, is also slow, which necessitates the development of alternative nutrient sources for some primary producers, such as pitcher plants and other carnivorous plants that extract their nutrients from the insects they trap.

Fig. 4 The patterned ground of the tundra biome in the North Slope borough of Alaska results in soil organic matter inputs from vegetation restricted to mosses, grasses, and sedge species. Decomposition rates are slow due to the saturated conditions and cold temperatures resulting in high carbon sequestration potential. Photo credit: Ken Hill, National Park Service. Public Domain.

Tundra systems

The permanently frozen horizon of material in the soil system in the tundra causes diversity in the soil biology to become severely limited. In areas where the ice layer is too shallow to allow tree roots to penetrate far enough for stability, the surface of the landscape is dominated by short grass species, mosses, and lichens. Because there is a physical barrier to drainage across the landscape, much of the upper horizons of the soil remain saturated where there is sufficient precipitation throughout the year. This cold and wet soil environment results in very slow rates of decomposition and an accumulation of SOM above the permafrost (Fig. 4). For this reason, the boreal and tundra systems contain the largest amounts of SOM on the planet.

Evidence suggests that decomposition starts in early spring before the first snow melt due to microbial activity. The base of the snow pack is often at freezing point throughout the winter. As that temperature creeps above freezing, microbes will become active in the soil pores and begin to decompose material from the previous year. The largest factor in the diversity of the soil macro- and meso-fauna is the moisture content of the soil across microenvironments. While the more mesic soils have more protozoans, the mesofauna (collembola, mites, and enchytraeids) tend to have greater densities where the soil is drier (Kane, 1996).

Conclusion

The influence of biology on soil development is not an easy topic to discuss because the influence of other soil forming factors varies so widely across the landscape. The soil species diversity, density, and even the timing of activity of the species can change dramatically with latitude, altitude, and other physical and chemical influences. It is the biological system in the soil that allows carbon to be either stored or recycled to the biology above ground through conversion to carbon dioxide and back to the plant through photosynthesis, and which processes the organic contributions in such a way that allows other life forms to access the nutrients they need to survive. Plants enlist the help of all other flora and fauna within the soil to survive when obtaining some of their resources from either above or below ground, essentially bridging the line between earth and life. While our understanding of the intricate details of the biological influences on the soil is still being developed, the appreciation and importance we have for what we know the soil biology does is very large.

Abstract

The transformation of parent material is the starting point for soil development and as such it is one of the key environmental factors determining soil formation. Most parent materials are mineral matter, although there is a distinctive group of soils developed from organic materials such as peat or coral sand. In the first stages of soil development involving the weathering of minerals, the parent material is a major influence on the nature of the soil; in most soils this influence reduces through time. In addition to non-organic parent materials from in situ geological materials, many have formed from eroded and redeposited materials.

Key points

- The diversity of soil parent materials is large consisting of residual, transported and organic materials.
- In many environments soils are developed in relatively thin layers of transported superficial materials overlying the underlying solid geology.
- Reworking of soil parent materials within the landscape frequently results in complex soil patterns.
- The soils that develop at a site are the result of complex interactions of the soil forming factors.
- Soil parent material is subject to weathering; in some parent materials their distinctive features may persist, in others they may be modified and markedly different following weathering.
- Soil parent material was recognized as a major feature at the highest levels in early soil classifications; in more recent soil classifications such as Soil Taxonomy and the World Reference Base soil parent material is mostly used at lower levels to distinguish soils.

Introduction

Parent material is the material from which soils have developed. While some soils are developed from organic materials the vast majority have developed from mineral materials, and it is in this context that parent materials are most frequently discussed. For mineral soils the parent materials include both in situ consolidated and unconsolidated materials, and materials which may have been subject to soil development, transported and deposited with soil development beginning afresh at the new location. [Table 1](#) broadly summarizes this range of materials. The mineral matter derived from these materials is the starting point for soil development. In the early stages of soil development the parent material will normally have a major influence on the nature and properties of the soil developed, but with increasing development this influence frequently decreases. For organic soils the primary parent materials are decomposing materials of various plant types and macro-, meso- and micro-fauna.

Residual parent material develops in place from the underlying rock. It may have experienced intense weathering over a long period of time. In a warm and humid climate it is likely to be thoroughly oxidized and well leached with most readily soluble materials removed. Rock materials subject to intense weathering in humid climates often have a distinctive reddish or yellowish color due to the oxides of iron. In cooler climates and specifically in drier climates, weathering is less intense and oxidation and hydration of iron are less visible. In drier climates leaching is limited and alkali and alkaline earth cations may be present in larger concentrations.

Transported materials form a significant proportion of global soil materials. Colluvial debris is transported by gravity and locally by water. Under gravitational transport the materials are generally poorly or weakly sorted e.g. rock falls, talus slopes and avalanche

Table 1 Classification of soil parent materials.

Residual Parent Materials		
I	Igneous rocks and crystalline schists A. Acid rocks (gneiss, phyllite, mica schists etc.) B. Neutral rocks (diorite, microdiorite, andesite, etc.) C. Basic rocks (pyroxene, amphiboles, serpentine, etc.)	
II	Transition forms A1 } B1 } C1 }	Deposits of the coarse disintegration products of Class I. Mainly gravel moraines, arkose gravel and sandy alluvial deposits.
	A2 Quartzite B2 Shales C2 Calcareous shales	
III	Sedimentary Rocks A Quartz sandy rocks(sandstones, sands) B Clayey rocks (fine clay, clay, loam) C Carbonate rocks (limestones, dolomites, marl, etc.)	
Transported Parent Materials

material. Where materials are moved locally by water, material is transported from upper parts of the landscape and deposited in the lower parts. The nature of these colluvial materials depends on the source of material higher in the landscape, but in general finer materials are preferentially transported.

Alluvial deposits are materials transported by streams and rivers and include flood plain deposits, alluvial fans and deltas. Flood plain deposits are laid down when the streams or rivers overtop their banks and flood surrounding areas. There is a distinct pattern of deposition, with coarser materials, sand and gravel, deposited closest to the channel and finer materials, silt and coarse clays, further away. In environments where there has been a fall in the base level of the river, the river may cut through the alluvium and the resultant features are left as terraces. Terraces are a feature of many river basins in northern hemisphere environments where there were numerous changes of base levels during the Pleistocene period. Alluvial fans occur where a river or stream leave a narrower valley with a steeper grade and descend to a broader low angle plain. The sediment is deposited as a fan, with coarser material deposited first. Deltaic deposits occur where rivers and streams enter lakes, seas or oceans. There is a reduction in velocity of the flow and hence the carrying capacity of the watercourses; the suspended material is deposited to form a delta.

Much of Northern Europe, North America and parts of Northern Asia were covered by ice sheets during the Pleistocene (10,000 to 2,500,000 years ago). The ice cover was not constant during this period and in warmer interglacial periods the ice cover was often less than 20% of their maximum extent. While there were local variations, it is generally accepted that in Europe and North America there were up to 20 distinct periods of maximum ice advance over a period of 1 to 1.5 million years separated by warmer interglacial periods when ice coverage was considerably reduced. With the advance of the ice sheets the weathered material at the surface (earlier soil development) was removed together with unweathered materials which were physically eroded from the solid rock. Frequently this material was carried considerable distances by the ice sheets and when the ice retreated these transported and eroded materials were deposited forming a veneer, known as drift, a few meters to tens of meters thick over the local rock. This material became the future parent material for soil development and is often markedly different from the underlying solid rock material. Locally, other glacial drift materials such as glacial outwash and lacustrine deposits were deposited associated with the often complex glacial landscape. As an example, Boulton et al. (1985) describe the nature of glacial geology and the associated patterns of deposition in the later mid-latitude ice sheets, providing a description of the wide range of materials present at the surface as parent materials for soil development.

Wind blown (eolian) deposits are found extensively as soil parent materials. Today the source of these materials is principally from sparsely vegetated environments often associated with deserts. In much of the Northern Hemisphere there are extensive eolian deposits, which are associated with the Pleistocene period. During this period fine unconsolidated materials, principally silt and fine sand, were picked up by wind from outwash surfaces and arid zones in locally deglaciated or periglacial zones and transported long distances before being deposited. This material is known as loess and it is estimated that there are deposits of varying thickness across 10% of the Earth's surface. These loess deposits are very variable in terms of thickness, ranging from layers tens of meters thick as on the Loess Plateau of Central China to a few tens of centimeters thick. Soil development in this latter situation may take place

Fig. 1 (A) Hall Series – 60 cm of coverloam over morainic material; (B) Freckenham Series – Morainic material at the surface; (C) Sheringham Series – 110 cm of coverloam over morainic material. Photographs S. Nortcliff.

with two parent materials, the lower part of the profile developing from local geological materials or drift and the upper part from wind-blown deposits; these deposits have often been subject to weathering and soil formation processes prior to being transported. In some landscapes these thin veneers of wind blown material may also be subject to colluvial processes resulting in complex soil patterns. As an example, [Catt et al. \(1971\)](#) describe the distribution of wind-blown materials in the soils of northern Norfolk in the United Kingdom. These deposits are generally less than 1 m in depth and have been subject to subsequent erosion and deposition in the undulating landscape of the area.

A study by [Evans and Nortcliff \(1978\)](#) investigated the erosion and deposition patterns of the windblown deposits deposited in the Anglian Glaciation c. 450, 000 years ago that overlie gravelly morainic materials in an area of north Norfolk. This landscape consists of relatively flat crest surfaces with asymmetrical valleys ([Corbett and Tatler, 1974](#)). The soils identified as Hall Series on the flat crests and low angle slopes have a covering of between 50 and 70 cm of wind-blown fine sand and coarse silt (coverloam) overlying gravelly morainic materials ([Fig. 1A](#)). On the steeper slopes much of the windblown material has been eroded with the coarse morainic material at the surface; these soils have been identified as the Freckenham Series ([Fig. 1B](#)). In the valley bottoms, eroded windblown materials have accumulated with over 1 m-depth of fine sand and silt (coverloam) before the coarser morainic materials are encountered; these soils are identified as the Sheringham Series ([Fig. 1C](#)). These patterns are shown schematically in [Fig. 2](#). In many years these patterns can be seen from the air as crop growth is strong in the valley bottoms and exceptionally poor on the eroded slopes.

While these materials are broadly categorized as natural soil forming materials, increasingly in urban areas natural materials are moved around during development and frequently they are mixed with materials that might be broadly described as technogenic materials. Soil development begins afresh in these new materials which may be exceedingly diverse in character. Relocated natural materials arise when landscapes are levelled or excavated during construction projects, and the nature of the soil development that takes place subsequently on these relocated materials is highly dependent on their state during movement (in particular their moisture content) and how they were handled during extraction and placement at a new site. Technogenic materials result from human activity and are often used as fill materials, frequently with excavated natural materials applied as a thin veneer over them. These technogenic materials include building rubble, which often consists of brick and mortar debris, ashes from industrial processes such as coal fired power stations and incineration processes, slags from blast furnaces and steelworks, materials derived

Fig. 2 A schematic diagram of the distribution of coverloam in the Cromer Ridge landscape. Soils Data © Cranfield University (NSRI) and for the Controller of HMSO 2022 used with permission.

from household waste management, sewage sludge and industrial sludges. These materials are very diverse and some such as ashes and slags may have strongly alkaline pH values and may contain large concentrations of contaminants such as metals and complex organic materials which strongly influence the soils that develop and also their use.

Soil forming factors

The diversity of soils found across the Earth's surface, even from parent materials of the same or similar nature and composition, is because of the interaction of the processes of soil development with external factors. Soil development is a slow process with changes taking place over long time periods. Dokuchaiev (1883) in Russia, Hilgard (1914) in the USA and Crowther (1930) in the United Kingdom considered the nature of soil development and the influences of environmental interactions. They also noted that the same parent material may form different types of soil depending upon the environmental conditions at the site of soil development, particularly the climate and vegetation. Dokuchaiev expressed this in a broad relationship:-

$$s = f(\text{cl}, p, v)^t \text{ where } s = \text{soil, cl} = \text{climate, } p = \text{parent material, } v = \text{vegetation/biota}$$

These relationships were changing through time^t.

Jenny (1941) developed these ideas and presented them in his seminal work *Factors of Soil Formation* presenting the concept that the state of the soil system is defined by the interaction of independent variables or soil forming factors. These were presented by Jenny in a generalized environmental formula of soil forming factors;

$$S = f(\text{cl, o, r, p, t, } \dots),$$

where S is some attribute or measurable property of soil, f() means 'as a function of,' cl is the environmental climate, o is species or organisms (often this is subdivided in to plant species, v, and living organisms (both macroscopic such as burrowing animals and microscopic such as bacteria and fungi)), r is relief or topography (including hydrological variations such as water table depth across the landscape), p is parent material (the initial state of the soil system) and t is time (age of the soil, absolute period of soil formation), with additional unspecified factors. More recently, with the increasing influence of human activity on soil development it has been considered that we should recognize an anthropic factor as a strong influence on soil development in many areas.

When considering the soil forming factors and their influence on soil formation, it is possible to consider their influences at different spatial scales. In the early attempts at soil classification in Russia and North America the different scales of influence of the soil forming factors were identified in the broad structure of the classification systems (Dokuchaiev (1883) in Russia and Marbut (1935) in USA). The highest level of these classifications distinguished Zonal Soil where the determining factors of soil formation were identified as climate and vegetation (tundra, taiga, deciduous forest, wooded steppe, steppe, semi-arid, and tropical soils). These broad zones were distinguished at the continental scale. The second level was Intrazonal Soils where the dominant factors were parent material and topography (calcareous, saline and hydromorphic soils); these soils were often distinguished at scales of tens to hundreds kilometers. Azonal Soils were the third category where soil formation was not advanced and included soils developed in recent colluvium and alluvium; these were frequently distinguished at the local scale of less than 1 km. Glinka (1927) summarized this approach presenting a global view of the characterization and classification of soils. While providing a relatively straightforward starting point, this approach was unable to account for the complex interrelationships between the soil forming factors which resulted in the tremendous diversity of soils at the Earth's surface.

Increasingly the interrelationships of the soil forming factors and their influence on the nature of soils was recognized as more complex than those at the broad continental scale which was the focus in these earlier approaches. With time these many more subtle relationships were recognized at scales from hundreds to tens of kilometers and less as understanding developed. The factors and their interactions define the state of the soil system. The soil system has been defined as an arbitrary volume of the solum, a soil body, a pedon (the smallest three-dimensional body of soil with lateral dimensions large enough to permit the study of horizon shapes and relations in it). The soil system is open to energy and matter influxes and outfluxes. Influx of energy includes solar radiation, and heat and entropy transfer; outflux of energy includes heat radiation and the reflection of light. Influx of matter involves gases entering the system by mass flow (wind), water in liquid and solid forms, solids dispersed in air or dissolved or dispersed in water, and organisms that migrate into the system.

Within this suite of properties in mineral soils, the parent material is the initial mineral material from which the soil will develop and is the initial state of the soil system.

Weathering

The fundamental process transforming mineral soil parent material into soil is weathering. Rock weathering is the in situ alteration and fragmentation of rock materials exposed to the atmosphere or hydrosphere. Weathering consists principally of the physical and chemical alteration of rocks or minerals at the Earth's surface, although it is increasingly recognized that biological processes also contribute to this alteration in many environments. These processes may occur simultaneously or in sequence. For example, the initial physical breakdown of rocks increases the surface area accessible to chemical and biological weathering.

Most rock materials when exposed at or near the Earth's surface are in an environment markedly different from that in which they were formed and when exposed are not in equilibrium with their environment, this is particularly true for igneous and metamorphic rocks. Weathering is their transformation to a form that is more stable under these near surface conditions. The weathering process results in the transformation of primary minerals into smaller particles and secondary minerals together with the release of other constituents which may be removed by leaching.

Physical weathering is the rupturing of rocks as a result of physical stress. As rocks are exposed and the confining pressures removed they may expand and rupture along fracture planes. Water may penetrate fractures and on freezing can cause pressure which may cause disintegration. Plant growth may contribute to physical weathering as a result of the pressure exerted by roots, which can sometimes rupture the rocks and force blocks apart.

Chemical weathering resulting in the transformation of the original mineral material brings about many of the changes that give the soil its distinctive characteristics. Chemical weathering occurs because exposed rocks and minerals are not at equilibrium with their environmental conditions. Weathering produces materials that are more stable in these near surface environments, but may continue to change as the pedo-environmental conditions change. There are several principal processes of chemical weathering:

Dissolution is the process whereby water soluble salts (sodium chloride, NaCl; gypsum, $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$) dissolve through attachment of H_2O dipoles to cations and anions of the crystal framework with the removal of ions in solution. Weathering of carbonate rocks gives a distinctive suite of soils. Calcium carbonate is quite soluble under surface conditions where CO_2 levels are enhanced. In this reaction the resulting calcium and bicarbonate ions are both soluble and readily leached from the system, therefore, the properties of the soils resulting from these dissolution processes depend strongly on the nature of any insoluble fraction in the parent rock. (see Fig. 3 below).

Hydrolysis is the decomposition of salts, if formed by a strong base and a weak acid or a weak base and a strong acid; water dissociates into H^+ and OH^- ions that attack (hydrolyze) the salt. Hydrolysis is a key process in chemical weathering, particularly of silicate and aluminosilicate minerals. This process is slow and the reactions occur predominantly on the surface of the crystals. Slightly acidic water together with a variety of ions present in solution react with these minerals. For aluminosilicates the products of these processes are the clay minerals, which play a key role in determining the nature and properties of soils and their development.

Fig. 3 Rendic Leptosol, developed on Jurassic Limestone under mature beech woodland (*Fagus sylvatica* L.), Germany. Photograph: Jörg Prietzel.

Oxidation is the process by which an element loses an electron resulting in an increase in the positive valency of the element. Examples include oxidation of the reduced elements iron (Fe^{II}), silicon (Si^{II} , Si^{I}), manganese (Mn^{II}) by O_2 (oxygen) in the presence of H_2O and microorganisms to the corresponding oxidized states Fe^{III} , Si^{VI} , Mn^{III} and Mn^{IV} . Iron is the most commonly oxidized element in the soil environment, and is associated with the distinctive brown or reddish brown colors of many soils. The presence of Mn darkens the soil color.

Hydration and dehydration are processes by which water molecules are added to or removed from a mineral, resulting in the formation of a new mineral. A common reaction in soils involves the reaction of hematite with water to form goethite. In well drained soils the presence of hematite gives the soils the distinctive reddish and reddish brown colors.

Ion exchange between the soil solution and soil mineral is an important process in the transformation of one clay mineral to another.

Influence of soil parent material on soil properties

The rate at which soil development occurs depends principally on climate, including rainfall and temperature, but the other factors will also influence the nature and rate of development.

In the early stages of soil development the parent material often has an over-riding influence on the nature of the soil properties which develop, but through time the effects of other factors increase and the dominant effect of parent material is greatly diminished or eliminated. Two of the important soil properties that are inherited from soil parent material are the mineral composition of the soil and its texture. Although these properties are often altered with time during soil development, in some soils the influence of the parent material persists. Wilson (2006) compared the nature of soils developed on two common but contrasting soil parent materials, granite and basalt, through time. The general characteristics of the soils developed from these two contrasting parent materials were markedly different in the early stages of development, but through time and increased weathering many of these contrasts have persisted but some have become less marked. The sand mineralogy of soils developed from granite tends to consist of quartz, K-feldspar, Na-feldspar, muscovite, biotite and amphiboles, whereas for the basalt-derived soils it consists of Ca-feldspar, orthopyroxene, clinopyroxene, olivine, magnetite and smectite. In the early stages of soil development there would be marked differences in the clay mineralogy of the soils developed from these two parent materials. Granitic soils are dominated by illite and Al-hydroxy interlayered vermiculite as well as vermiculite itself. In contrast, soils developed on basaltic materials contain little or no illite and often contain smectite, either directly inherited from the parent rock or derived due to pedogenesis. In old well weathered soils derived from both groups of parent materials these marked differences in clay mineralogy disappear, and both groups show broad similarities with kaolinite, halloysite, gibbsite and iron oxides becoming most prevalent. There are marked differences in the soil physical characteristics of the soils from the two parent materials, differences which persist as the soils are weathered. The clay content in soils derived from basaltic rocks is consistently higher than in those developed from granitic materials and these differences persist in older well weathered soils. Young soils derived from granitic materials have higher porosity and hydraulic conductivity, but lower water retention and water availability than those derived from basaltic materials, and these differences persist with time. In terms of the soil chemical properties, the pH of young soils developed on granite parent materials tends to be below 5.5 and is often below 5.0. In contrast, the pH of young soils developed on basaltic materials is generally within the range of 5.0 to 7.5, and for older more weathered soils the pH range is normally between 5.0 and 6.5. The percentage base saturation shows similar patterns; in young granitic soils it is often <20% but >60% in young basaltic soils. In older soils these values are lower, but marked differences persist.

Where a parent material is rich in calcium carbonate its weathering and the leaching of soluble by-products usually results in distinctive soils where the small proportion of insoluble residue in the material results in soils with a small mineral fraction and a large proportion of organic matter. Fig. 3 is a Rendic Leptosol from Germany developed from Jurassic Limestone under a stand of mature beech (*Fagus sylvatica*). The soil has a shallow organic rich layer (<25 cm) including limestone fragments overlying fragmented Jurassic Limestone. Further analytical details are provided in Prietzel et al. (2021) and Prietzel et al. (2022).

Soil formation

Soils develop from parent materials that are exposed at the Earth's surface as a result of changes which occur within the soil system. These parent materials can be bedrock exposed at the Earth's surface or relatively unconsolidated materials which have been deposited in the landscape. The result over time will frequently be a soil profile exhibiting a sequence of distinctive layers, known as soil horizons. The lowest strata of the soil profile are known as the C horizons; these horizons show the least alteration from the nature of the original parent material. The process of transformation from rock materials into soil profiles is known as soil genesis.

While the processes that bring about changes in the material and development of a soil profile are complex, Simonson (1959) suggested a simple framework of broad processes:-

- Additions of materials
- Removal of materials
- Transformation of materials
- Transfers of materials within the soil

The principal influence of parent material on this development is expressed through the transformation of these materials as a result of weathering in the upper part of the profile, which has properties that are progressively different from the original parent material and with less weathered material deeper in the profile. In dynamic landscapes there may also be additions of material to the soil surface through alluvial, colluvial or eolian processes that result in complex soil profiles. Within the soil profile there may then be transfers of material, for example, clays may be transferred from upper horizons and deposited in clay enriched argillic horizons. Similarly, iron, aluminium and organic matter may be transferred from upper soil layers and deposited deeper in the soil in podzolic or spodic horizons. In some arid and semi-arid environments salts may be transferred from solutions deeper in the soil to be deposited in saline or alkaline layers near or at the soil surface.

Parent materials and soil classification

As mentioned above, much of the early work on soil classification focused upon the zonal concept which had been developed in Russia by Dokuchaiev (1883) and in the USA by Marbut (1928) and Baldwin et al. (1938). As knowledge about soils increased it became increasingly difficult to accommodate soils satisfactorily into this classification structure. There was a move away from a soil forming factor-based system of classification toward a quantitative property-based system. This culminated in 1960 with the "Seventh Approximation" (Soil Survey Staff, 1960) where the higher levels of the classification (Soil Orders) are distinguished by the presence or absence of one or more diagnostic horizon. This publication provided a basis for discussion and in 1975 Soil Taxonomy (Soil Survey Staff, 1975, 1999) was published. Soil Taxonomy is a strongly hierarchical system with 12 Orders at the highest level and a further 5 levels of subdivision with series at the lowest level. There was a shift away from the soil forming factor approach as the basis of soil classification in Soil Taxonomy, however, the factors as key elements of the classification are evident at many levels of the classification.

Soil parent material is used at various levels of Soil Taxonomy to identify soil taxa. At the highest level of Soil Order it is used to distinguish Andisols, Entisols and Histosols. Andisols are soils formed in volcanic ash and defined as containing a high proportion of glass and amorphous colloidal materials. Entisols are broadly described as soils that show very limited soil development and consequently are relatively unaltered from their parent material. Histosols are derived from organic materials. Parent material is also used to define taxa at lower levels, for example at subgroup level with modifiers including Andic, Arenic, Lithic and Paralithic.

While Soil Taxonomy is widely used there is another globally important soil classification system the World Reference Base for Soil Resources (IUSS Working Group, WRB, 2014). This latter system consists of a flat hierarchy with only two levels. At the first level, 32 soil reference groups (RSGs) are recognized, with the second level distinguished by modifiers of the RSGs. Leptosols, Regosols and Fluvisols are the RSGs which represent soils that are at the initial stages of soil development and soil parent material is a dominant influence on the nature of the soils. Andosols are soils formed in volcanic materials. Arenosols are soils where the texture is sandy because of the sandy texture of the parent materials. As with Soil Taxonomy, the WRB distinguishes Histosols as a distinct group of soils developed from organic materials.

Summary

The five soil-forming factors – parent material, climate, biota, topography, and time – determine the distribution and nature of soils over the Earth's surface. Mineral components of many soils are inherited from parent materials, while others develop in situ during weathering and pedogenesis. Morphological properties of soil develop as a result of the processes acting on parent materials. Soil scientists have attempted to show the controlling effects of parent material on soil properties to the extent that it is proposed as an independent soil-forming factor and defined as the state of the soil system at time zero of soil formation. The physical body of soil and its associated mineralogical and chemical properties provide the basis for the operation of the soil forming processes under the influence of the other soil-forming factors. Previously weathered rock or even a previous soil could be considered parent material, which can be modified over time. Parent material exerts its strongest influence on the soil-forming process of immature soils.

Abstract

Loess is commonly defined as a distinct body of mainly wind-blown silt and covers c. 10% of the Earth's surface, mainly in the temperate zone. Silicate silt predominates over carbonate, clay and some fine sand, making loess a favorable soil parent material. Thick loess deposits are well-mapped and important archives of Quaternary landscape and human evolution, whereas thin loess deposits and dust admixtures into soils are rarely studied, despite their usually positive influence on soil properties.

Key points

- Loess is commonly defined as the accumulation of wind-blown dust, but in situ processes are essential to provide its coherent structure.
- Loess covers c. 10% of the Earth's surface, mainly in temperate zone lowlands, outside areas glaciated during the Pleistocene.
- Loess is mainly (coarse) silt with minor clay and sand admixtures, lightly cemented by clays and carbonates.
- Loess soils are among the most fertile soils worldwide and thin covers/admixtures of mineral dust to parent materials usually have favorable effects on soil functions.
- Loess–paleosol sequences are widespread terrestrial paleoenvironmental records and can also preserve open-air Paleolithic sites.

Introduction

Loess, frequently defined as an accumulation of wind-blown dust, covers c. 10% of the earth's surface (Fig. 1; Busacca and Sweeney, 2005). This common estimate excludes thin loess deposits of a few decimeters thickness, and dust contributions to soils and soil parent materials. Loess is widely recognized as a parent material for fertile soils, geotechnically distinct ground in densely populated regions, Quaternary paleoenvironmental archive, and preserver of Paleolithic heritage.

Loess is a term initially adopted from people of the Upper Rhine Valley (SW Germany), where loess is an important element of landscapes and soils. The first scientific description of loess, originally interpreted as a water-lain deposit, dates back c. 200 years and highlights its silt loam texture and earthy structure (Leonhard, 1824). Since then, there have been controversies concerning the definition of loess, due to its intermediate position between sediment and soil (Sprafke and Obrecht, 2016). The predominance of silt results from preferential particle selection by wind, the coherent structure is due to "loessification," a weak cementation, attributed to initial pedogenesis or weak diagenesis.

Being an earth surface deposit, loess and related sediments are frequently affected by reworking and pedogenesis. It is difficult to draw boundaries between typical loess and loess-like deposits (loess structure, but no purely aeolian deposit) or loess derivatives (altered/reworked loess or loess-like deposits). By considering genetic criteria it is possible to subdivide loess sediments into several subtypes (Koch and Neumeister, 2005). Pécsi (1990) lists 10 criteria to define loess, but in most cases a simple definition of loess as a distinct body of mainly wind-blown silt is sufficient.

Fig. 1 Global distribution of major loess deposits, deserts and mountains and extent of ice sheets during the last glacial maximum (LGM; c. 24,000 years ago). Compiled with Adobe Illustrator[®] using shapefiles and satellite imagery (for desert and mountain extent) projected on naturalearthdata.com, assembled with mapshaper.org. Loess extent digitized from Li et al. (2020), LGM ice extent from Ehlers et al. (2011).

Genesis

The formation of loess involves silt production, transport, deposition and post-depositional processes. From a sedimentological perspective, aeolian transport and deposition are essential to create the silty texture of loess. A pedological perspective highlights in situ processes creating loess structure, which is important from a geotechnical point of view. Fig. 2 conceptually integrates both views.

Silt is the predominant particle size of loess and is produced from larger particles by a number of processes (Wright, 2001): Silt-sized mineral particles are a common byproduct of physical weathering in deserts or periglacial environments, but may also be released by chemical weathering. During fluvial or aeolian transport, silt can be formed by comminution and abrasion. Among the most efficient processes to produce large quantities of coarse silt, typical for loess, is glacial grinding (Smalley, 1995). Muhs and Bettis (2003) differentiate two main models of loess formation from particle production to aeolian deposition, the “classical” glacial and the desert model; an important difference being that the desert model requires no glacial grinding in silt formation (Lancaster, 2020). Next to silt production, recycling of older deposits contributes significantly to silt availability.

Fig. 2 Loess and the rock–sediment–soil continuum. Thick blue arrows indicate the main transport agents from the place of sediment production; the final transport is by wind. Local reworking is excluded from this simplified scheme. Thin gray arrows show aeolian transport modes adapted from Pye (1995). Common grain sizes for the respective transport mode are indicated in light gray (S: sand, Si: silt, C: clay; c: coarse, m: medium, f: fine). Note that available grain sizes differ across environments. Residual soils form from local parent materials without a significant contribution of mineral dust. These may be humid tropical soils far from deserts, but also temperate zone soils that formed from the loess of Pleistocene glacial periods.

Free silt minerals can easily be entrained and transported by wind as mineral dust, whereas sand may be too heavy and clay too cohesive. Direct aeolian mobilization of silt from production areas is possible, but in the complex sequence of processes that lead to the formation of loess, usually at least one phase of non-aeolian transport takes place before the final aeolian transport and deposition of mineral dust (Wright, 2001). This explains the location of major loess deposits close to large rivers, especially those draining centers of extensive Pleistocene glaciations (Smalley et al., 2009).

Deserts are the main contemporary source of aeolian dust, which contributes to soils in their surroundings and even to distant ecosystems. For example, Saharan dust reportedly provides nutrients to the Amazon rainforest. In semi-arid regions, partly connected to large river systems, loess forms from deposits of deflated silt (Lancaster, 2020). In periglacial environments of Alaska and Northeast Siberia, silt deflated from dry beds of braided rivers can accumulate as distinct sedimentary bodies. However, most loess deposits in the currently humid to semi-humid temperate zone formed during glacial periods when large ice masses reached far into the temperate latitudes, which were largely dominated by tundra or (cold) steppe ecosystems drained by rivers loaded with sediment.

Next to source properties, transport mode and distance determine the granulometry of aeolian deposits (Fig. 2; Pye, 1995). Close to deflation centers, sand and sand loess deposits transported by saltation and lifted by turbulent airflow are common, whereas with increasing distance over tens of kilometers, silt transported through suspension predominates. Fine silt can be transported over thousands of kilometers. Loess usually has a mixed provenance, with a predominance of regional components in the coarse silt mode and variable finer components deposited after long-range transport.

Deposition of mineral dust takes place when wind-speed is reduced, which is behind topographic obstacles and strongly supported by local vegetation. Considerable dust deposition typically occurs in polar to subtropical semi-desert/steppe environments. Herbs, grasses and cyanobacteria trap silt particles which are successively incorporated into the permanent silt deposit. The transformation of loose silt to loess is commonly referred to as “loessification,” a complex (bio)physiochemical process between pedogenesis and diagenesis that remains insufficiently studied (Sprafke and Obrecht, 2016).

Typical loess consists essentially of windblown silt. Yet, within the depositional environment, some short-scale reworking by water may occur, potentially involving the admixture of non-aeolian material, which may differ in grain size (Vandenbergh et al., 2018). Loess-like deposits are not purely aeolian deposits with a coherent loess-like structure (Sprafke and Obrecht, 2016). Reworking of loess and loess-like sediments creates loess derivatives, dominated by silt, but lacking loess structure. The distinction between different types of loess sediments is not always straightforward and is further hampered when these are overprinted by pedogenesis during phases of morphodynamic stability.

Distribution

There is no global agreement on how to define loess and related sediments, and regional loess maps rely on the standards of the geological surveys involved in mapping. By convention, loess less than 1–2 m thick is not mapped on most geological maps. This is unfortunate for pedologists and ecologists because even a few decimeters of loess strongly influence the pathways of pedogenesis and finally soil properties (Lorz et al., 2013). To derive European loess maps, Bertran et al. (2016) used topsoil silt data to model loess distribution, whereas Lehmkuhl et al. (2020) compiled data from numerous regional geological or pedological surveys. Global scale loess maps only approximate the main loess regions characterized by thick loess sediments.

Li et al. (2020) provide a global compilation of loess distribution and information on the key genetic processes of the different loess landscapes (Fig. 1). The most remarkable loess landscape is the Chinese loess plateau with more than 300 m-thick loess in the middle reaches of the Yellow River, which drains (semi-)arid and mountainous regions further west. Between lowland deserts and mountains of Central Asia, loess can reach more than 100 m thickness. Loess that is tens of meters thick drapes Western Siberia, Southeastern Europe, and Midwest USA. Continuous loess covers Eastern Europe and Northern Argentina. The European loess belt is subdivided by numerous low mountain ranges.

Rare occurrences of desert margin loess are reported from NW India, Nigeria and Namibia. Periglacial regions drained by the larger rivers in Alaska and NE Siberia provide modern analogs of Pleistocene loess formation in the temperate zone. Outside the common definitions for loess are alluvial silts that have formed by periodic flooding, e.g. in the vast Hungarian lowlands, but appear loess-like upon drying. Loess mapped in subtropical regions of China, e.g., in the lower reaches of the Yangtze River may rather be accretionary soils or even soils with aeolian admixtures. Yellowish tephra deposits intercalated by paleosols in Central Mexico (Sedov et al., 2009) may be called volcanic loess, but are never indicated on global loess maps. Tropical loess reported for NE Argentina and S Brazil has caused strong controversies, as it is most likely deep red soil (Morrás et al., 2009).

Properties

Loess sediments are characterized by the predominance of silt, with a distinct mode in the coarse silt fraction (20–60 μm), less commonly in the medium silt fraction. Sandy loess contains more than 20% sand and clayey loess more than 20% clay (Pye, 1995). Loess is usually homogenous, without any clear stratification. The mineralogical composition depends on the source region, but a predominance of quartz (40–70%) is typical for most loess regions. Common minerals include feldspars, micas, carbonates, oxides and clay minerals (e.g., kaolinite, illite). While there are regional variations in loess geochemistry, its average composition resembles the upper continental crust (Taylor et al., 1983).

From a pedological point of view, the content of carbonate in loess is specifically relevant. Calcite and to a lesser degree dolomite, are comparatively quickly leached from loess in a humid climate, facilitating advanced chemical weathering and leaching of further base cations, once the carbonate buffer is removed. Depending on the dust source, carbonate contents of loess range from 5% to >30%. Primary loess free from carbonate is rarely reported, e.g., from New Zealand (Muhs and Bettis, 2003).

Loess has a coherent structure caused by the aggregation of silt particles by clay and/or carbonate bridges. At outcrops, loess can form steep cliffs of more than 10 m in height. The massive structure is interrupted by numerous pores (mainly medium to fine), mainly created by former grass root channels that sum to 40–55% of the volume of loess. Bulk density of loess is between 1.5 and 2.0 g cm⁻³. Typically, loess has a light-yellow color, related to the presence of colorless transparent (quartz) or white minerals (feldspar, carbonate) and yellow limonite (iron oxide). Deviations from this general description are related to reworking (leading to a loss of structure) and advanced degrees of pedogenic structuring and pigmentation.

Temperate-zone loess soils

Due to its porosity and mineralogical composition, loess is easily altered into soil by transformation, turbation and translocation processes. Bioturbation and the amount of water moving through initially porous homogenous loess determine the extent of alteration and redistribution of solutes or colloidal particles. Terrestrial soils from loess are instructive examples to illustrate the influence of climate on soil properties. The concept of soil zonality was developed 150 years ago for the soils of Russian loess landscapes, with soil properties largely determined by the climatic conditions and related ecosystems (Paton et al., 1995). Soil development from loess is the subject of numerous soil science textbooks; herein it is referred to temperate-zone soil types after the IUSS Working Group WRB (2015).

Under well-drained conditions in a temperate humid climate (potentially under deciduous forest), bioturbation and humification, carbonate leaching, oxidation, silicate weathering and clay transformation as well as clay translocation lead to the formation of brown-colored soils with clay enriched subsoils (Luvisols; Fig. 3A). Reduced subsoil drainage results in enhanced redoximorphic

Fig. 3 Loess, soils and paleosols. Black and white scales in Figures A–D mark the thickness of aeolian silt. (A) Protostagnic Luvisol from >2 m-thick loess in S Germany. (B) Stagnic Luvisol from 1.35 m-thick loess overlying reworked sand loess in SW Poland. (C) Albic Stagnic Luvisol from c. 1 m-thick loess overlying weathered penultimate glacial till in NE Wisconsin, United States. (F) Fossil Reductaquic Cryosol (commonly referred to as tundra gleys) in loess profile of SE Poland. (G) 22 m-thick last glacial LPS Toshan (N Iran) with mainly weakly developed paleosols above the last interglacial pedocomplex. (H) Middle- to Lower Pleistocene interglacial paleosols of the >40 m-thick loess-paleosol sequence Stari Slankamen (N Serbia). (B) Photo by J. Waroszewski.

processes, eventually leading to the formation of Stagnic Luvisols (Fig. 3B and C) or Stagnosols. Retisols that form under cooler climate than Luvisols have characteristic pale cracks/tongues that probably relate to past periglacial processes (Fig. 3D). In a less humid, more continental climate (potentially under steppe), carbonate leaching is reduced and weathering limited, thus bioturbation and humification lead to the formation of thick dark horizons, typical of Phaeozems (decalcified) and Chernozems (Fig. 3E). Under even dryer conditions, descending transport is limited or in semi-arid regions is replaced by ascending solute transport; typical soil types are Kastanozem or Solonetz/Solonchak, respectively.

Luvisols, Phaeozems and Chernozems from loess are among the most fertile soils worldwide. While both, sandy and clayey soils provide few advantages and many disadvantages, (silty) loams are the most suitable for growing a wide range of agricultural products (Catt, 2001). The downside of millennia of agricultural production in loess landscapes is long-term soil erosion, facilitated by the considerable erodibility of silt. Its saturation with water can lead to a collapse of loess structure and rather rapid erosion by downslope transport or through piping (Busacca and Sweeney, 2005). The loss of well-structured surface soil also accelerates this problem, as water easily erodes fresh loess with its largely coherent structure. Fertile colluvial and alluvial soils in regions characterized by centuries to millennia of agriculture frequently result from downslope/downstream transport of loess soil.

Dust, soil, (paleo)environments

In (semi-)humid temperate regions, present day loess soils formed after the end of major dust accumulation around 10,000–15,000 years ago. This temporal separation of loess and soil formation is due to profound environmental changes at the transition between the Pleistocene and Holocene, resulting in a transition from morphodynamic activity to stability (Kemp, 2001). Soils of the (semi-) humid temperate zone are residual soils that form from local parent material (e.g., loess) without significant dust admixtures during their formation. The same is likely for soils of the central humid tropics; e.g., Sahara dust reaching the Amazon rainforest is not traceable in soils, but has a positive effect to the nutrient budget of local vegetation. Closer to Holocene dust sources (e.g., the Sahara desert) are soils with detectable quasi-constant aeolian admixtures (e.g., in some Mediterranean or savannah regions). These unusually have large silt contents compared to locally formed parent materials and are good indicators for dust contributions to soils, but additional results from mineralogy and geochemistry are required for reliable conclusions. Accretionary soils form by quasi-constant sediment admixture, but pedogenesis is still strong enough to be imprinted into the substrate. The boundary between accretionary pedogenesis and loess formation is poorly defined (Fig. 2).

While the effect of present-day mineral dust additions to soils and ecosystems is being studied increasingly, the effect of dust admixture to loess parent materials remains poorly recognized. In situ or reworked Pleistocene weathering products outside the mapped loess regions contain variable amounts of windblown dust that may strongly influence pathways of pedogenesis and soil properties (Lorz et al., 2013). While loess formed in temperate zone lowlands during glacial periods, surrounding highlands experienced frost weathering, cryoturbation and solifluction under periglacial conditions. Slope deposits (cover beds) active during the Pleistocene, but stabilized by vegetation and soil formation during the Holocene, contain variable admixtures of mineral dust. These may be difficult to trace if present in small quantities or strongly affected by pedogenesis. At the margins of loess areas are gradual transitions to loess-like deposits and slope deposits with clearly detectable dust admixtures. Landscape position and geological context as well as soil texture, mineralogy and geochemistry help to quantify the extent of dust admixture to parent materials (Fig. 3A–D; Waroszewski et al., 2019).

Well-mapped thick loess deposits frequently show alternations of loess units and buried soil horizons, so called loess-paleosol sequences (LPS). LPS form by the interplay of dust sedimentation and pedogenesis due to changing paleoenvironments (Kemp, 2001). The intensity of paleosol development, usually referred to as degree of chemical weathering, is foremost a function of past moisture availability and the overall duration of pedogenesis; paleosols within LPS indicate past environmental conditions, if the duration of pedogenesis is established (Bronger, 2003). Strongly reduced horizons in temperate zone LPS, commonly referred to as tundra gleys (Fig. 3F), indicate the presence of permafrost that prevented drainage during topsoil thawing in summer (Reductaquic Cryosols). Pale brown to gray horizons indicate weak weathering, typical of interstadials (Fig. 3G), whereas paleosols with a development similar or more advanced than the present day soil typically indicate interglacial periods (Fig. 3H) (Bronger, 2003).

Paleoenvironmental interpretations from paleosols are challenging if there is weak age control. In the last decades new geochronological methods (e.g., optically stimulated luminescence dating) have delivered increasingly robust estimates on the timing of sedimentation and the duration of pedogenesis. Loess paleosols with complete horizonation are rarely preserved. Topsoils may be reworked along slopes or completely lost by erosion during the transition from morphodynamic stability to activity. Careful field observations and micromorphology help to distinguish an in situ paleosol (remnant) from a pedosediment, eventually overprinted by pedogenesis. Polypedogenesis is common in areas with comparably low rates of dust sedimentation, where soil forming processes change without being separated by loess units. Only the combination of sedimentological and paleopedological approaches unravel the full potential of LPS as key archives of terrestrial paleoenvironmental evolution and dust dynamics during the Quaternary (Kemp, 2001). Additionally, loess preserves important Paleolithic open-air sites, allowing the integrated study of human and environmental evolution.

Time scales of soil formation and a potential influence of relict and fossil soils to surface soil properties remain poorly established. Compared to hard rock, loess is comparably easily transformed into soil, leading to the formation of thick steppe or forest soils in a relatively short time (1–2 m in 10,000 years). In landscapes with thick loess covers, fertile loams may appear to stakeholders as an endless resource. It is important to raise awareness about the processes and time scales of soil (neo)formation to

promote sustainable use of soil. To quantify rates of soil production, knowledge on loess formation, dust contributions to mapped lithologies or current dust admixtures to soils is essential. It is important to note that deep, fertile temperate zone soils largely result from past morphodynamics and long-term pedogenesis and may not be restored quickly under present day environments. Thin loess mantles may be quickly lost by erosion, leaving less favorable geological substrate behind.

Conclusions

Loess is among the most widespread terrestrial deposits and parent material of fertile soils. Due to its complex formation and widespread occurrence with variable properties, there exists no universally accepted definition of loess. A simple definition as a distinct body of mainly windblown silt is in most cases sufficient. Aeolian deposition of mineral dust explains the silty texture, while the coherent structure is related to weak in situ cementation. Loess is an easily erodible and weatherable substrate and therefore frequently reworked and overprinted by pedogenesis, which makes the mapping of loess sediments challenging. Thin loess mantles remain frequently overlooked, despite their usually positive influence on soil properties. Thick loess deposits and intercalated paleosols are important archives of quaternary climate, landscape and human evolution.

Abstract

The environmental conditions under which soils and their properties develop are governed by combinations of the climate, biota, geology, and topography, which operate over time. Time affects soil-forming processes by controlling their duration and degree of soil development. Thus, we can differentiate between ‘young’ and ‘old’ soil in each ecosystem based on degrees of chemical and physical weathering and the resulting expression of soil properties. The amounts and distribution of biotic and abiotic soil constituents are often used to determine the relative age of a soil and differences in their properties can be explained as a function of time.

Glossary

Calcium carbonate Carbonate mineral that forms coatings on soil that react with an acid to form carbon dioxide gas.

Evaporation Water on the Earth’s surface or in the soil absorbs heat from the sun to the point that it vaporizes or evaporates and becomes part of the atmosphere.

Horizon An individual layer within the soil which has its own unique characteristics (such as color, structure, texture, or other properties) that make it different from the other layers in the soil profile.

In situ Latin for ‘the original position’.

Soil horizons An identifiable soil unit due to color, structure, or texture.

Soil profile The ‘face’ of a soil when it has been cut vertically that shows the individual horizons and soil properties with depth.

Soil texture The way soil ‘feels’ when it is squeezed between the fingers or in the hand. The texture depends on the amount of sand, silt, and clay in the sample (particle-size distribution), as well as other factors.

Translocation The movement or transfer of material from one part of the soil profile to another.

Transpiration Water in plants escapes or transpired into the atmosphere as the leaf stomata open to exchange carbon for oxygen.

Key points

- The environmental conditions under which soils and their properties develop are governed by unique combinations of the climate, biota, geology, and topography, which operate over time.
- Time affects soil forming processes by controlling their duration and degree of soil development.
- Relative soil age may be determined by the extent of chemical and physical weathering and the resulting expression of soil properties.
- The amounts and distribution of soil organic carbon, carbonate, and various other elements, and the amount and distribution of clay and its mineralogy are often used to determine the relative age of a soil.
- Soil chronosequences provide an opportunity to determine relative ages of landscapes that are 100,000 to 1,000,000 years old and a chronologic framework to contextualize numerical age by use of absolute dating techniques.

Introduction

Thousands of soil types at the Earth's surface are composed of unique biological, chemical, and physical properties. These properties are the direct result of a complex set of soil-forming processes that are conditioned by distinctive environmental factors. The environmental conditions under which soils and their properties develop over time are governed by combinations of climate, biota, geology, and topography (Jenny, 1941).

Climate affects soil development, as moisture and temperature control the rate of biological, chemical, and physical processes. The effect of biota is primarily related to controls on inputs and outputs of organic and inorganic materials; the effect of topography relates to the changes in temperature and precipitation due to differences in elevation and slope angles. The chemical and mineralogical composition of the parent material influences such key soil properties as nutrient status, alkalinity or acidity, and texture (Hillel, 2008; Jenny, 1980).

Climate, biota, topography, and parent material have a direct effect on soil-forming processes, whereas time has an indirect effect. Time affects soil-forming processes by controlling duration and, therefore, the degree of soil development (Yaalon, 1983). We can differentiate between 'young' and 'old' soil in each ecosystem on the basis of degrees of chemical and physical weathering and the resulting expression of soil properties.

Key soil properties that vary with time

The amount and distribution of soil organic carbon (SOC), carbonate, and other key elements, and the amount and distribution of clay and corresponding mineralogy change as a function of time in a generally consistent and predictable manner (Koop et al., 2019) (Fig. 1). The amounts and distribution of these soil constituents are often used to determine the relative age of a soil.

Once vegetation is established in an ecosystem, biotically-related properties such as SOC are continually added through both above- and below-ground inputs of living and dead plant tissues. Older soils are expected to have a greater accumulation of SOC than younger soils (Gile, 1970). The accumulation of SOC eventually reaches a steady state where inputs equal outputs, and there is no further net accumulation with increasing soil age (time) (Lawrence et al., 2015; Wang and Amundson, 1996; Merritt et al., 1991). The length of time needed for SOC to reach a steady state varies among environments but is within a relatively short time frame of 10^2 – 10^3 years (Buol et al., 1997).

The accumulation of abiotic properties such as calcium carbonate (CaCO_3) in soils over time is generally limited to soils of semiarid and arid regions, where precipitation of carbonates occurs under conditions typical of dry soil environments, high pH, and high evapotranspiration. The increased production of carbonic acid (H_2CO_3) under humid conditions results in the dissolution of CaCO_3 and a decrease in CaCO_3 over time (Lal et al., 2021). Sources of calcium in arid and semiarid soils may be from in situ weathering of calcium-bearing minerals or atmospheric deposition. Unlike SOC, CaCO_3 accumulation may not reach a steady state, but continues to increase through time (Wang et al., 2016; Monger and Rachal, 2013).

The most abundant elements in soils, excluding oxygen and carbon, are silicon, aluminium, iron, magnesium, calcium, sodium, and potassium. Although these elements have varying solubilities, their relative abundance is a direct function of the degree of soil weathering (Dixon and Weed, 1989), which increases through time and soil development (young, intermediate, old). In general, the simple soluble cations, magnesium, calcium, sodium, and potassium, are readily released from the soil through weathering processes and are easily leached (Fig. 2a). Unless there is an input of these elements to the soil system from the atmosphere or some

Fig. 1 The effect of time on the development of biotic (e.g., soil organic carbon) and abiotic (e.g., calcium carbonate) soil properties.

Fig. 2 The effect of time on soil development: (a) the loss of chemical soil constituents, (b) the transformation of phosphorous, (c) pH and clay mineralogy, (d) and biologically available water.

other mechanism, their quantities steadily decrease as a function of time (Chadwick et al., 2022). Soil silicon, aluminium, and iron exist primarily as relatively insoluble hydroxides and are leached at a slower rate than the simple soluble cations (Fig. 2a).

Phosphorus is an element which exists in soils in a variety of organic and inorganic forms, the distribution of which indicates the relative weathering of the soil profile, and therefore, soil age. As soil development begins and the soil matures, primary mineral sources are depleted, and organic and secondary occluded mineral forms of phosphorus accumulate (Turner and Laliberté, 2015; Crews et al., 1995; Walker and Syers, 1976) (Fig. 2b).

The accumulation and distribution of soil clay minerals are indicators of soil age (Arduino et al., 1986). Clays accumulate through time as a function of the atmospheric deposition of dust, translocation from superjacent soil horizons, and in situ formation of secondary clay minerals. Layers of accumulated clay can form in as little as a few hundred years if there are significant atmospheric inputs in the form of dust or mud rains. Rates of accumulation are largely a function of translocation and weathering in areas of decreased atmospheric input. Clay-enriched horizons can develop within 10^3 – 10^4 years, depending on environmental gradients from humid to arid.

Clay mineralogy is partly a function of soil age because, over time, soils become increasingly depleted in soluble framework cations and silicon, major constituents of clay minerals. Clay minerals, therefore, often form in a recognized sequence. The youngest stages of soil development commonly consist of 2:1 type clay minerals (i.e., illites and/or chlorites) that weather early in the sequence to other 2:1 type clays (i.e., smectites and/or vermiculites). Weathering of 2:1 clay minerals to 1:1 clay minerals (e.g., kaolinite) occurs in the intermediate to late sequence of soil development. Iron and aluminium oxide clay minerals result in the oldest soils that have undergone the longest time of soil formation (Arduino et al., 1986) (Fig. 2c).

Biologically available water is optimized during the intermediate stage of soil development (Salley, 2015) (Fig. 2d) where the accumulation of clay and organic compounds enhances aggregation. Aggregates provide the foundation for soil structure which influences productivity and organic matter additions through its effect on aeration and root proliferation. While the weathering process over time results in clay accumulation, water is held too tightly in the micropores of clay for plants to access it (Easton and Bock, 2016). Thus, water available for transport and plant uptake depends on the macropores created during aggregation where water is more likely to infiltrate (Beven and Germann, 2013). Loamy soils have the greatest biologically available water because they drain excess water quickly and store it in medium- and small-sized pores and in organic matter (Easton and Bock, 2016). Over time, the soil will accumulate clay and organic matter, and develop structure (i.e., aggregation) to enhance porosity that supports water infiltration, storage, and bioavailability.

The preceding discussion theoretically describes the effect of time on soil development when climate is a constant variable. Given the same duration of soil formation, a soil forming in a warm, humid environment will have soil properties that are significantly more developed, and which appear to be older than a soil forming in a cool, dry environment. Increasing precipitation causes increased chemical and physical weathering, effectively mimicking the effect of a long period of soil formation in a relatively short time period. In humid areas, where precipitation exceeds potential evapotranspiration, biological and chemical weathering processes rapidly transform organic and mineral matter. Leaching transfers materials down, and eventually through, the soil profile. The same soil-forming processes operate in drier areas where precipitation is less than potential evapotranspiration; however, the availability of water limits the intensity and duration of these processes (Birkeland, 1999).

Studies of time and soil formation

The differences in properties among soils can be explained as a function of time if those soils are forming in the same climate, maintain the same type of vegetation, have developed from the same or similar parent materials, and are located at the same topographic position. In other words, time is the only factor that varies between the two soils being compared. Soil properties, developed as a function of time, are used as a proxy of age (Markewich et al., 2017). Climate, biota, parent material, and relief can be held constant under a limited number of circumstances, including the comparison of soils developing on stream terraces sequentially incised by a single river system (Haan, 2014). In this case, the soils of the floodplain are developing in the most recently deposited material and are the youngest; the soils on the highest stream terrace relative to the floodplain are the oldest (Loadholt, 2002) (Fig. 3). Such a series of related terrace soils, which differ only with respect to their duration of formation, are called a chronosequence (Stevens and Walker, 1970). Soils developing on chronosequences show broadly similar trends in morphology with time, including: (1) a thickening zone of organic matter accumulation; (2) increasing pedon thickness; (3) increasing horizon complexity; and (4) development of zones of secondary mineral accumulation. Trends 1–4 continue until the soil begins to degrade due to weathering. Many soils will not follow this predictable model which correlates dated terraces to the development of soil forming processes and properties over time; instead, unpredictable geomorphic processes result in non-linear soil development that does not correlate to absolute age (Huggett, 1998; Haan, 2014).

Soil chronosequences determine relative ages of landscapes that are 100,000–1,000,000 years old and also provide a chronologic framework to contextualize numerical age (by use of absolute dating techniques) (Markewich et al., 2017). Greater relevance to the chronosequence concept is provided where material for absolute dating techniques is not available. Ideally, absolute dating of the parent material anchors (to a maximum soil age) the relative age assessment determined by soil development indices. Absolute dating methods include optical luminescence dating (Markewich et al., 2017) and radiogenic techniques, such as radiocarbon analysis (soils <40 kyr) and U-series dating (soil >40 kyr). The latter methods require the availability of stable soil organic matter and pedogenic calcium carbonate, respectively. Other methods include dating by biostratigraphic age and amino acid racemization which, according to Wehmiller and Miller (2000), can be used as a semi-quantitative tool to estimate the relative age of molluscs in

Fig. 3 Soil chronosequence developing in a semiarid ecosystem. The youngest soil is at the lowest elevation above the floodplain; the oldest is at the highest elevation. The soil ages are, Holocene (<10,000 years), Pinedale (13000–600,000 years), Pre-Bull Lake (300,000–600,000 years).

marine terrace deposits (Haan, 2014). Meteoric cosmogenic ^{10}Be has the potential to record soil residence time and numeric soil age (soils >40 kyr) when no other chronometer is available; this method estimates the minimum required time for a soil to form (Markewich et al., 2017; Willenbring and von Blanckenburg, 2010).

Conclusion

Chronosequences are problematic in that, over millennial time scales, a constant climate cannot be assumed. Numeric soil age, or duration of soil development, can also be difficult to establish. Despite these obstacles, chronosequences provide an excellent opportunity to study the influence of time on soil formation. The combination of relative and absolute dating techniques is promising for the reconstruction of landscape history.

Abstract

Soils form the dynamic foundation for terrestrial life on Earth. In contrast to the slow rate of natural soil formation in diverse landscape settings, soil change by humans is often more rapid and far-reaching. Land use changes soil properties and processes both directly and indirectly through agriculture, urbanization, industry, mining, war, and climate change. People can enhance soils for uses such as agriculture and engineering, but their actions often degrade soil health, leading to lower productivity and ecosystem function. Knowledge about anthropogenic transformations of soil is essential to foster soil conservation, remediate degraded soil, and promote sustainable land use.

Key points

- Objective: to introduce readers to anthropogenic soil change and its importance.
- Humans have far-reaching impacts on soil resources through agriculture, urbanization, industry, mining, war, and other land use.
- People also change soils indirectly by altering the factors of soil formation, such as through climate change.
- Knowledge about anthropogenic soil transformation is essential in efforts toward soil conservation, fostering soil health and soil security, and sustainable land use.

Technical Nomenclature

A horizon	Surface mineral horizon with some organic matter accumulation
Argillic horizon	Subsurface diagnostic horizon with significant clay accumulation
B horizon	Subsurface mineral soil horizon (several kinds)
C horizon	Relatively unweathered, unconsolidated mineral horizon or layer (or soft bedrock), usually beneath the active zone of soil formation
Fragipan	Dense, brittle subsurface horizon
Irragic horizon or soil	Anthropogenic horizon formed by long-term irrigation and accompanying additions of sediment
Paleosol	Soil formed in a past geologic period
Petroplinthite	Hardened or cemented horizon of highly weathered, iron-rich soil
Plaggen horizon or soil	Thick, organic-matter rich anthropogenic horizon formed during long-term cultivation by additions of manure, sod, and other materials.
Spodic horizon	Refer to Spodosol below

The following terms are nine out of the 12 soil orders of the US soil classification system (Soil Taxonomy)

Alfisol	Mineral soil that is relatively low in organic matter, relatively high in base cations, and with subsurface clay accumulation
Entisol	Undeveloped mineral soil
Gelisol	Mineral or organic soil of cold regions, with permafrost
Histosol	Organic soil
Inceptisol	Mineral soil with initial, but relatively weak development
Mollisol	Mineral soil with thick, dark, organic matter-rich surface horizon, high in base cations
Oxisol	Intensively weathered mineral soil, typically developed on old land surfaces in intertropical regions and distinguished by residual accumulations of kaolinite, iron oxides, and aluminum oxides.
Spodosol	Mineral soil with subsurface accumulation of organic matter, aluminum, and commonly iron
Ultisol	Highly weathered mineral soil that is relatively low in organic matter, relatively low in base cations, and with subsurface clay accumulation

Introduction

Humans, like many other organisms, are active agents of soil formation. Because soils comprise the dynamic, vibrant skin of the Earth's terrestrial surface, people have always interacted with, and therefore changed, soils and the course of their formation. While soils are subject to major change and even destruction by natural forces on the scale of geologic time, changes resulting from human activity usually occur on a much shorter time scale. Human impact on the Earth's land, water, atmosphere, and life has become so pervasive that the current geologic age is recognized as the Anthropocene (Brown et al., 2017; Richter, 2020).

People have had an impact on the soil in a multitude of ways and extents, through farming, building, mining, war, and recently climate change (Capra et al., 2015; Dazzi and Lo Papa, 2015; Howard, 2017). In some cases, human activities enhance soils for particular uses such as agriculture and engineering. However, in other cases, the interplay between humans and soils has resulted in degradation of soil health, leading to lower productivity and environmental function. Recognizing that soil use is literally and figuratively the ecological basis for civilizations and that soil resources are essentially nonrenewable on the human time scale, understanding soil formation and its transformation by humans is imperative for developing agricultural and natural resource sustainability, and for protecting environmental quality.

Scales and scope of human impacts on soil formation

To understand the effects of humans on soil, it is helpful first to provide a frame of reference by considering soil-formation processes and their rates in natural environments. From the perspective of pedology, the study of soil formation, soil is a complex assemblage of mineral and organic materials formed at the Earth's surface. In spite of the increasing impact of human activities on soil and the likelihood that all of the Earth's ecosystems have been influenced to some degree by humans, many soils still retain their basic morphology imparted by natural processes and environmental factors. A hallmark of soil formation is the differentiation of horizons (layers). Soils are developed and organized into horizons by complex, interrelated physical, chemical, and biological processes that are determined by the factors of soil formation: climate, organisms, geology, topography, and time. The morphology of every soil is the expression of those fundamental processes interacting with one another over multiple spatial scales (from micrometers to kilometers) and temporal scales (from days to millennia). Horizons at the surface (A horizons) are often enriched with organic matter, while deeper horizons (B horizons) may have accumulations of clay minerals, calcium carbonate, metal-organic complexes, or other materials. Formation of A horizons is relatively rapid because organic matter accumulates in a few centuries to a millennium. Formation of B horizons commonly takes many thousands of years to become fully expressed. In this sense, soils can range from young to old. As soil formation progresses, soils generally tend to become increasingly anisotropic as they differentiate into greater kinds and numbers of horizons.

Landscape stability is a prerequisite for the development of soil horizons to proceed. Even so, disturbance and change are integral to the functions of all natural ecosystems and their soils. Soils, landscapes, and associated biological communities are changed by disturbances ranging from minor perturbations such as low-intensity fires to major events such as volcanism, as well as long-term climatic and environmental change. On the geologic time scale, soils are subject to major alteration, destruction, and renewal. In contrast to the relatively slow pace of natural soil development, soil changes resulting from human activity are often more rapid and far-reaching. Human-caused change may be so fast and irreversible that the affected soil bears little resemblance to its original form, such as in cases of severe erosion or soil excavation and filling in urban engineering. Human impacts often reverse the anisotropic trend of soil formation, making soils simpler, less organized, and more homogeneous.

A wide array of land use and other human activities have altered the paths of formation in many soils (Table 1). Corresponding soil changes also vary greatly in kind, intensity, time and spatial scale, and significance for soil and environmental quality

<i>Human agents of soil change</i>	<i>Examples</i>
Agriculture and forestry	
• Crop and animal agriculture	Tillage, fertilization, cropping, flooding, irrigation, drainage, terracing, grazing
• Forestry	Altered vegetation type and cover, harvesting operations
• Off-site effects	Erosion and sedimentation, causing soil contamination and burial
Cities and industry; buildings, roads, and other structures	Excavation, urban cover, artificial fills, land leveling, paving, pollution
	Dams and reservoirs, polders, dikes, mounds, other artificial landforms and fills
Mining and other earth and water resource extraction	Soil removal for pits and quarries, erosion and sedimentation associated with excavation, mixing and inversion of earth materials, acid drainage, land disturbance to build pipelines and well pads, groundwater pumping, reclamation
War and military operations	Bomb craters, military transport and engineering, tunneling, contamination by chemicals and radioactive elements
Human-linked environmental change	
• Global climate change	Increased atmospheric CO ₂ and other greenhouse gases, climate warming, increased climate variability and extremes
• Desertification	Vegetation loss or change, accelerated wind and water erosion, salinization
• Acid rain	Soil acidification and other chemical changes

(Tables 2 and 3). Human actions that change soil may act directly or indirectly by changing both soil morphology and underlying soil-forming processes. They may be intentional changes based on land-management strategies to increase soil productivity, or they may be rearrangements of landscapes and soil materials to construct buildings, roads, and other structures. Conversely, they may be unintended changes that can lead to degradation such as soil erosion and burial under sediment. Indirect soil change may result from off-site processes physically remote from the affected soil, such as subsidence following groundwater pumping or downstream sedimentation. In land uses such as agriculture, surface horizons are usually more altered than subsurface horizons, while engineering activities often change the entire sequence and character of natural soil horizons. Engineering activities lead to some of the most intensive effects by removing soils entirely and replacing them with different earth materials, as well as by reshaping landforms or constructing new ones. Agriculture and engineering merge in management practices such as in paddy rice production and terracing of slopes, which also involve major geomorphic and soil change.

Some human activities such as agriculture have influenced soil processes and morphology for thousands of years (Macphail and Goldberg, 2018; Winiwarter, 2014), while others such as global climate change have come to the forefront recently (Horwath and Kuzyakov, 2018). The impacts of anthropogenic climate change on soil formation and distribution are large because climate is a major determinant of soil formation over time, acting through multiple pathways. Some anthropogenic impacts on the environment, such as acid rain and other pollutants, lead to less visible chemical and biological changes, while processes such as desertification result in more sweeping changes through loss of vegetative cover, desiccation, wind and water erosion, and salt accumulation.

In their response to human actions, soils differ in their resistance to change and resilience, that is, their ability to rebound toward their original state. Processes of human-caused soil change may be reversible or irreversible, and the resulting changes may be ephemeral to permanent (Johnson and Lewis, 2007). Response depends on both external factors, such as the type of impact and environmental conditions, and on internal soil properties like texture and mineralogy. For example, soils with uniform textures or that are rich in organic matter tend to be resistant to compaction. After many thousands of years of natural formation, some subsurface soil horizons disrupted by deep plowing may return to their original condition in a few years (e.g., clay-rich argillic horizons), whereas more indurated horizons such as silica-cemented duripans remain fragmented for longer.

Evaluating human impacts on soil formation

Human-caused soil change has been studied by pedologists in several ways (Dudal et al., 2002; Wills et al., 2017). Hans Jenny and others framed their views in the context of the factors of soil formation, placing humans within the biotic factor, while recognizing the unique role of human culture as distinct from other organisms (Amundson and Jenny, 1991). Jenny showed that human land use often alters soils through changes in the other soil-forming factors. For example, irrigation alters arid land soils by changing the climate factor, effectively increasing precipitation (Bidwell and Hole, 1965). Other researchers set humans apart from the natural factors of soil formation to emphasize the extraordinary scale and rate of anthropogenic effects on soils (Yaalon and Yaron, 1966). In working with drastically altered soils such as mine soils and urban soils, pedologists have defined new soil taxonomic classes, because these soils bear little or no resemblance to their original state (Soil Survey Staff, 2014).

How is soil change detected and measured? While large impacts on soil may be obvious, such as wholesale change or destruction of soils and landscapes in mining, terrace building, or urban development, it is still difficult to quantify changes to soil forming factors that may be longer-term. Soil changes due to land use conversion or management practices are often more subtle and

Table 2 Scope of anthropogenic soil change and response. Bracketed terms illustrate range end members.

Soil Change Characteristics and Range	Examples
Causes of soil change may be	
- Direct - Indirect	Compaction Slower or diverted water movement and reduced soil water storage after compaction
- Deliberate - Unintended	Fertilization, liming, irrigation Nutrient depletion or imbalance; salinization
- Constructive - Destructive	Plaggen soil; terraced soil construction Accelerated erosion, sulfide oxidation with drainage or exposure, salt/sodium buildup
Magnitude and extent	
- Low impact - High impact	Conservation tillage; minor soil change from low-intensity fires Urban expansion; land filling
- Soil property or horizons - Whole soil effect	Thinning of A horizon by erosion Removal of entire soil by intense erosion
Duration and rate	
- Short-term/ephemeral/reversible - Long-term/permanent/irreversible	Alleviation of plow pans by freeze-thaw; liming Urban soil; mine soil; Laterite/plinthite hardening with exposure
- Slow rate - Fast rate	Agric horizon development Oxidation following drainage
Response of soil to human impact	
- Susceptible - Resistant	Low-pH soil susceptible to acid rain Neutral to high-pH soil buffered against acid rain
Change outcomes for soil health and use	
- Beneficial - Neutral/benign - Degradation (of productivity and environment)	Organic matter addition Fertilization that balances crop removal of nutrients A horizon erosion

Table 3 Spatial scales of soil change.

Soil components	Approximate spatial scale (m)	Examples of impacts
Physical, chemical, and biological components	10^{-10} – 10^{-4}	Retention of pollutants such as heavy metals, pesticides, industrial solvents, and human and livestock drugs
Morphological properties	10^{-3} – 10^{-2}	Soil structure degradation; changes in texture, color, porosity and pore distribution
Horizons	10^{-1} – 10^0	A horizon erosion
Whole soils (pedon)	10^0 – 10^1	Plaggen soils; salinized soils; liming that changed Ultisols to Alfisols
Soil-watersheds-landscapes-biosphere	10^2 – 10^7	Broad changes in Mollisols, Histosols, Gelisols and other soil orders due to processes such as accelerated erosion and soil organic carbon loss, as well as climate change

difficult to document than dramatic wholesale landscape changes. Histories of soil change may be difficult to reconstruct, complicated by the physical, chemical, and biological legacy of multiple land use activities and changing environmental conditions. Both inherent properties and disturbances are spatially and temporally variable, making it difficult to quantify the kinds and amounts of soil change across scales.

The most straightforward approach to assess anthropogenic soil change is to monitor soil in one location over time. Soil changes from agriculture have been monitored using controlled experiments at a few locations such as Rothamsted Experimental Station (United Kingdom) and Morrow Plots (Illinois, United States) for more than a century. An alternative approach is called “space-for-time substitution,” in which soil change by humans is measured at multiple locations either in reference to undisturbed soils that serve as benchmarks, or by comparing soils inferred to have been the same originally but that have now diverged due to different land use histories (Wills et al., 2017). For example, Fenton and others in Iowa, United States correlated declines in crop productivity with soil properties that were originally similar but experienced varying degrees of erosion (slight to severe, resulting from agriculture) at different locations (Fenton et al., 2005). Finding truly comparable sets of reference and altered soils is challenging and imprecise, and may not be possible in some situations. Pedogenic process models can also be used to understand and evaluate soil change with land use and management. When paired with careful site selection and carefully constructed hypotheses, these models provide powerful tools for linking soil formation and soil properties to disciplines such as soil management, biogeochemistry, and geophysics.

Recently evolving techniques in proximal sensing and remote sensing allow the detection and synthesis of soil change from molecular to global scales. New sensor technology provides rapid, inexpensive detection and resolution by many wavelengths of the electromagnetic spectrum. At sample and field scales, these sensors allow data collection at many more locations than traditional laboratory analyses. At continental scales, geographic information systems and remote sensing allow coverage of wide areas and detection of change through repeated data collection over time. For example, global models of soil carbon stocks have been improved through increased use of mid-infrared assessment of soil carbon concentrations, and those values have been extrapolated through remotely sensed images and geographic models using predictive digital soil mapping techniques.

Evaluating ancient agricultural soils up to about 1000–2000 years in age has extended the time perspective on anthropogenic soil change (Sandor and Homburg, 2017). Much can be learned about long-term human effects on soils, and about successes and failures in soil use and management, from studies of past cultures at archeological sites, as well as studies of contemporary traditional cultures who have lived on the same land for many generations. Investigations of past and present traditional land use contribute information for evaluating soils on longer time scales that are inherent in the concept of sustainable land use, as well as for modeling and predicting the future condition of land resources.

Changes in soil properties and processes resulting from human activities

To facilitate an appreciation of the many ways people alter soil, and depend on soil for sustenance and support (Goudie, 2013), soil changes are presented here in the context of the type of land use or other human activity. Examples from agriculture, engineering for urban development, mining, waste disposal, war, and global environmental change are selected to represent the myriad of ways people change soil. It is important to recognize that human effects on soil are complex because soils are dynamic systems with interrelated components; they are themselves part of ecosystems within the Earth’s biosphere. Soils vary in their sensitivity to disturbance and thresholds for change. Individual land-use practices can affect many soil properties in a cascading process, and different land uses may initiate similar processes of change in soils. Soils may be changed by more than one land-use practice simultaneously or asynchronously. Land uses and their variations often differ in the way they impact soils in terms of magnitude, intensity, spatial extent, rate, and duration.

Agriculture

Agriculture has profoundly and extensively affected soils since its inception over 10,000 years ago (Kuzyakov and Zamanian, 2019; Winiwarter, 2014). In this discussion, agriculture is framed broadly to include all plant and animal production for food, feed, fiber, and fuel, including crop and livestock farming, as well as forestry. All of these land uses rely on many kinds of soil worldwide.

Some soils are so impacted by agriculture that their original horizons are wholly transformed or buried. Examples of truly anthropogenic soils are plaggens of northern Europe that mostly date to approximately 1000 years ago, during the Middle Ages (Fig. 1). These constructed surface horizons, which can be a meter thick, are the product of centuries of cultivation and additions of organic materials such as manure and sod. Soils that have been similarly transformed through management practices such as terracing and long-term applications of fertilizing materials are found in other regions with long histories of intensive agriculture such as Southeast Asia and the Andes. In the Amazon Basin, anthropogenic Amazonian Dark Earth (or terra preta) soils were created over long periods through incorporation of biochar and other organic materials. They have much higher fertility and crop productivity than the more common acidic and highly weathered soils (Oxisols and Ultisols) of the region.

In contrast to both the intent and effect of constructed soils, many soils on slopes have been damaged by erosion accelerated by agriculture, some to the point of obliteration or deep burial under eroded sediments through mismanagement. Surface horizons, which generally contain the most plant nutrients and organic matter, are the most immediately vulnerable to erosion. Those soils with well-developed, organic matter-rich surface horizons such as Mollisols are especially subject to major change. The

Fig. 1 Plaggen horizon (approximately 1 m thick) from The Netherlands, created by long-term organic matter additions and cultivation, burying a natural Spodosol. Reproduced from Soil Survey Staff (1999) *Soil Taxonomy*, 2nd edn. U.S. Department of Agriculture-Natural Resources Conservation Service. Washington, DC: US Government Printing Office.

transformation of Mollisols by erosion to soils classified in other orders such as Alfisols, Inceptisols, and Entisols has been documented for ancient and contemporary agriculture. A key reason for increased soil erosion is the loss of protective vegetation cover as natural ecosystems such as forests or prairies are converted to agricultural use. While accelerated erosion is difficult to quantify on regional to global scales, estimated average erosion rates on cropland range from about 12 (United States) to 30–40 (Africa, Asia, South America) metric tons per hectare annually, which is much higher than natural rates of erosion. Human-induced water and wind erosion are estimated to have resulted in the major degradation of approximately one-quarter of the world's arable land.

As surface horizons are eroded, subsurface horizons or bedrock effectively rise closer to the surface and may become exposed. Their incorporation into the topsoil under moderate to severe erosion alters soil properties such as color, structure, and texture, often causing a decline in soil quality. If subsurface horizons are problematic for plant growth, serious degradation of productivity can ensue. In some tropical regions such as West Africa and Southeast Asia, exposure of horizons of cemented, iron-rich clay (petroplinthite) through erosion has resulted in abandonment of agricultural land. Erosion of Ultisols with highly weathered, acidic horizons of clay accumulation in warm, temperate to tropical environments has significantly reduced soil productive potential. Even in thick sedimentary parent materials that are considered “forgiving” to erosion, productivity can diminish through exposure or the occurrence of dense or cemented horizons and layers at shallow depths that limit rooting, decrease available water capacity, or greatly slow drainage. For example, thick deposits of loess (wind-blown sediment rich in silt) such as in China and the Palouse and Midwest regions of the United States are favorable for crops but are particularly susceptible to erosion. Erosion rates in loess can reach 100 metric tons per hectare per year, exceeding natural erosion rates by one to two orders of magnitude. This has resulted in the loss of A horizons, followed by the exhumation of buried soils (paleosols) or dense, brittle fragipans at shallower depths that reduce productivity.

Erosion also alters soil formation away from the eroded sites. As eroded sediments are transported downslope, soils in the lower terrain of watersheds may become buried by sediment that does not reach streams. Studies in several regions have measured burial of original soils by sediment that is centimeters to meters thick. Also, the freshly deposited sediment constitutes another parent material in which soil formation may begin anew. An opposite situation occurs when natural sedimentation processes and renewal of soil fertility are impaired by dam construction, as on the Nile River where the Aswan Dam impedes annual flooding and deposition of nutrient-rich sediment. The extensive erosion and sedimentation that occur in many agricultural landscapes indicate that massive transformation of many soils is continuing. This situation underscores the need for documenting and responding to changes that undermine soil quality and productivity.

Because water deficiency or excess is of major concern in most agricultural systems, many soils have been altered by water-management practices. Some changes are direct, such as the effects of flooding soils for wet rice production, creating paddy soils with distinctive anthropogenic characteristics (Fig. 2; Zhang and Gong, 2003). “Irragric” soils in central Asia and other arid to semiarid regions have been highly altered by long-term irrigation, including the addition of suspended sediment in the irrigation water. Unintended chemical effects from irrigation in some regions have led to severe soil degradation through salt accumulation and transformation to saline or sodic soils. In contrast to paddy soil management, conversion of wetlands to row crop production by artificial drainage in regions such as the Midwest USA has changed soils from dominantly anaerobic to aerobic states, leading to

Fig. 2 Sample (approximately 5 cm thick) of paddy soil managed for wet rice production in Southeast Asia. Anthropogenic features include variegated colors from flooding and alternating reduction/oxidation, and vesicles formed from gases trapped beneath platy, puddled surface layers. Fig. 3 Accumulation of organic matter in topsoil (A horizon) during long-term natural soil formation, and subsequent rapid decrease following cultivation. Based on the work of Hans Jenny.

changes such as organic matter oxidation. In some areas of the world, many meters of organic soil thickness have vanished through oxidation processes, resulting in significant land subsidence. Such losses of sequestered soil organic carbon have contributed significantly to increased atmospheric CO_2 and to climate change.

More subtle agricultural impacts may not completely alter the original soil, yet over time cause significant change. For example, since the mid-19th century, conventional cultivation of organic matter-rich, prairie-derived soils (Mollisols) throughout the Midwest USA has led to marked decreases in organic matter in the upper soil horizons (Fig. 3; Jenny, 1984). Many Mollisols have lost approximately one-third to one-half of their original organic matter. In addition to erosion, a principal cause is the disruption of soil aggregates by cultivation, making previously protected humus accessible to microbial decomposition. Compared with native prairie ecosystems that are characterized by abundant organic matter and conservative nutrient cycling, agricultural soils have lower inherent fertility and are “leakier” with respect to nutrients such as nitrogen. Soil organic matter loss has a cascading effect on soil properties such as structure, by reducing aggregate stability and making soils more prone to compaction. Soil health can be restored through better management and regenerative farming techniques that use conservation tillage, diverse crop rotations, and cover crops to rebuild soil biological function and diversity, organic matter, and structural stability.

Cities and industry

The growth of cities and industry has profound impacts on soils and their continued formation (Bryant and Galbraith, 2003; Levin et al., 2017). Some of the impacts are direct; others are indirect. The creation of constructed urban soils is perhaps the most easily recognized direct effect of city growth on soils (Fig. 4). Constructed soils have distinct profiles that are typically the product of the cheapest engineering fill available at the moment of creation. Pioneering urban soil scientist Phillip J. Craul wrote that the history of urban development has been based upon the premise “dirt is dirt and it’s cheap.” These human-created soils may be highly stratified

Fig. 4 Three views of urban soils at Iowa State University (United States). Upper left: urban soil being created after the natural soil has been removed. Note natural soil profile in background. Upper right: older urban soil. Note several layers and artifacts (pipe, ceramics). Scale is 10 cm. Lower right: new urban soil. (Upper left) Photo by Julie McLaughlin. and composed of very different types of fill in terms of their texture, mineralogy, and chemistry. Total fill—and consequently soil—thicknesses can reach many meters, with a soil's maximum age corresponding with the age of the city. That is, a constructed urban soil in Rome, Athens, Mexico City, and Beijing can be several thousands of years old, whereas a similar soil in New York or Buenos Aires must be less than 500 years. Given the massive ongoing rise of new urban and suburban settings, many new hectares of urban soils are being actively created each year in every city. Many ancient cities occur on “tells,” human-created mounds or hills constructed over time as a city is rebuilt on top of its predecessor. In addition to unconsolidated fill, other construction materials used in urban soils include composted sewage sludge, municipal solid wastes, heavy metals, glass, plastic, and metal. Still others consist of clean sand mined from nearby rivers or topsoil transported from local farms. In other words, urban soils have an exceptionally high degree of disorganized variability.

A second direct impact of city development on soil formation is at the landscape scale as houses, gardens, parks, and streets replace the natural terrain. The result is fragmented landscapes, where soil-forming processes become controlled by constructed topographic, hydrologic, and ecologic factors. Although the morphology of many of these soils does not show the dramatic changes of their downtown counterparts, their soil-forming processes are considerably altered. This can be illustrated by considering two hypothetical, adjacent gardens: one growing turf that is heavily fertilized and irrigated, while the other is planted to conifer shrubs and trees but receives no fertilizers and extra water. Over time, the properties of the soils under these two gardens will diverge in response to their different microclimates (wet versus dry), biota, and chemical inputs. Like their constructed counterparts, they will be characterized by disorganized variability, although in this case the disorganization occurs at the landscape (i.e., garden-to-garden) scale.

A more drastic direct effect of urbanization on soils is “urban soil sealing,” when soils are covered with buildings, roads, and other constructions. Such soils are commonly altered by removal of surface horizons, by the addition of coarse particles or exogenous fill, and by compaction before being covered by impervious material. These alterations effectively arrest the normal processes of soil formation. Urban soil sealing reduces biodiversity, inhibits soil water infiltration and internal movement, and exacerbates problems of excessive runoff and flooding in urban areas.

The impact of cities and their continued growth on soil formation is increasing. Prime farmland and wild, often fragile, lands are the two most commonly converted rural lands (Fig. 5). In the United States the area of urban land increased from 6 to 26 million

Fig. 5 California: an example wherein soils are increasingly a product of human activities such as agriculture and urbanization. Compiled from a variety of sources, including US Census Bureau and US Census of Agriculture data and maps for c. 1900, 1950, 2000 and 2020 as well as several atlases and documents from the Great Valley Center and US Geological Survey's "Preliminary Assessment of Urban Growth in California's Central Valley." Updated by Audrey Jenkins.

hectares between 1945 and 1992 and is currently estimated to be about 120 million hectares due to dramatic increases in per capita urban land conversion. In a number of locations in California and the Eastern Seaboard "100-mile cities" are common with urban areas interwoven through express highways and suburbs. Urbanization in China and India is expanding even more actively than in the United States although the most affected areas today are in developing nations due their rapidly growing and urbanizing populations. The World Resources Institute notes urban land creation results in not only in-place soil loss but also creates regional environmental impacts that reduce food and water security. There is also distortion of real estate values within and outside the cities. On the positive side, many urban areas are experiencing growth in urban gardening and locally produced food on soils that only recently were considered agriculturally useless.

Industry, which often but not always overlaps with urban areas, directly and indirectly affects soil formation. Land excavation and drainage are two important direct agents of change. Dredging of wetlands as well as sediments from beneath shallow waters to improve harbors, build canals, and meet other commercial needs is an example of industrial excavation. The US Army Corps of Engineers and the Environmental Protection Agency estimate that more than 1 billion cubic meters of sediment are dredged annually around the globe with over 300 million cubic meters being dredged annually just in the United States. Dredging has three direct impacts with respect to soils and their formation. First, the dredging itself destroys whatever natural soil existed. Second, the dredged material—or "spoil"—is stockpiled and later used in soil construction. Soil created from dredge spoil may be used for buildings, roads, parks, farms, or even wild areas. Over time it will develop a sequence of horizons in response to its environment. The third pedological impact of dredging is oxidation of mineral and organic matter. This occurs because spoil that was excavated from below the water table is now directly exposed to the oxygen-rich atmosphere. In many cases, the oxidation is fairly benign in terms of soil properties and formation. A noteworthy problem occurs when the spoil contains sulfides. Exposure of sulfidic compounds to air results in the rapid formation of large quantities of sulfuric acid (H_2SO_4) in these soils. Such acid sulfate soils are also created when naturally sulfidic soils are drained. It is estimated there are potentially 24 million hectares of acid sulfate soils globally, with many located in prime settings for agricultural and urban development.

The indirect impacts of industry on soil formation are as manifold as the indirect impacts of urbanization. One of these is the addition to soil of contaminants such as lead, cadmium, and other heavy metals. In some locations these metals are deposited on soils as airborne contaminants that originated in factory or vehicle exhausts. In other cases they are added to soil directly and intentionally as constituents of fly ash and other wastes. “Land farming” refers to disposing of waste by applying and incorporating it into soil a few tons per hectare at a time. These soils are subsequently cropped, although the crops are not normally used for human consumption. Compounds that contain sodium comprise another class of industrial contaminant that changes soil morphology—ultimately creating sodic soils. This process is increasingly noted worldwide because of the huge number of industrial uses for sodium and sodium compounds (e.g., coolant in nuclear processes; fumigants; solvents in manufacturing of brass, paper, ceramic glazes, textiles, and fertilizers; and in food processing) and the frequency at which sodium wastes are applied to land. Radionuclides are another class of industrial contaminants that alter soil processes. For example, 8.4 million hectares around Chernobyl, Ukraine, remain contaminated by ^{90}Sr and ^{137}Cs from the 1986 nuclear reactor disaster there.

The influence of most industrial processes on soil formation is proportional to the intensity of industrial activity and distance of the soil from the industry. This means that soils in areas having numerous factories, automobiles, and other industrial activities are more highly enriched in contaminants than soils where there is little industry. Likewise, the magnitude of impact radiates out with distance from the source of impact.

New tools for identifying and mapping urban and industrially impacted soils have resulted from scientific advances in the geospatial sciences and soil classification systems such as Soil Taxonomy (United States) and the World Reference Base for Soil Resources.

Mining

Humans have mined the Earth for metals, minerals, and fuel for thousands of years. Since the 19th century, in particular, mining activities have radically transformed landscapes and altered natural soil development processes. Currently, about 80% of the Earth's mined area is located in 15 countries, and about 50% occurs in China, Australia, the United States, Russia, and Chile. Mining operations are estimated to cover approximately 57,000 km². Mining normally requires that the overburden of soil and its parent materials be displaced so that the product (e.g., mineral, rock, or coal) can be removed, concentrated, and transported off-site as economically as possible. Mining often results in large pits, high walls, and large accumulations of waste spoil, that is, unconsolidated overburden, smelting residue, and finely ground tailings from which the product has been extracted. At the Earth's surface, these landscape features and waste materials pose significant environmental risks due to subsidence, settlement, and slope instability. Spoil may also be contaminated with soluble metals. In addition, when some types of mine waste (overburden and tailings) are exposed to air and percolating water, oxidation reactions produce strongly acidic water with large metal concentrations, severely restricting subsequent biological activity. Unfortunately, abandoned mining sites are abundant in many countries. Their physical hazards and impacts on surface water and groundwater resources make remediation very expensive and severely limit return of the land to productive ecosystems.

In the late 20th century concern about mines and their waste prompted many nations to enact environmental-quality laws. For example, since enactment of the Resource Conservation and Recovery Act of 1976 and the Surface Mining Control and Reclamation Act of 1977 in the United States, planning for and completing reclamation of mined land has been part of every mining operation. Thus a number of practices are actively followed to allow a mined site to be used again for other purposes and to ensure that surface water and groundwater resources are protected. Reconstruction of soil at reclaimed mine sites is an example of the most radical of human impacts on soil formation.

Successful reclamation of mined land must address a number of large-scale environmental issues while at the same time creating a near-surface environment that promotes vegetative growth and movement of water through the watershed. Reclamation efforts may include topographic reconstruction, chemical treatment of spoil to remove or mitigate hazards, burial of acid-producing overburden and tailings, establishment of new vegetation, or construction of wetlands. Organic matter and plant-available nutrients are commonly lacking in spoil, so application of biosolids or other organic amendments to the reclaimed surface is often necessary. Applications of plant nutrients such as nitrogen, phosphorus, and potassium may also be required. A major problem in reclamation of coal and metallic ore mines is the oxidation of sulfide minerals and subsequent drainage and runoff of acidic water (Fig. 6). Acidic spoil, surface water, and seepage must be treated with large amounts of calcite or hydrated lime to neutralize acidity before vegetation can be established. Revegetation in the form of grasslands is a common approach to stabilize a reclaimed site quickly. However, reforestation may be more appropriate for a particular site, depending on its ecological context and plans for long-term use.

Large-scale topographic reconstruction of mined land is expensive, but it is essential to ensure that reconstructed soils maintain ecological and environmental quality. In some reconstructions, it is possible to approximate the general contours of the pre-mining landscape (Fig. 7). During the process of consolidating, grading, and shaping the new landscape, it is critical to control settlement, limit slope instability, and restrict surface erosion to minimize off-site damage of sediments and drainage.

Where the original materials were not systematically stockpiled during mining, reclaimed soils often display extreme variability in particle size and composition. Problems of heterogeneous mixtures of coarse and fine particles include both subsidence and inadequate water-holding capacity for plants to grow. For this reason, reclamation approaches may call for stockpiling excavated material to be restored in their natural sequence (e.g., bedrock-derived spoil placed below till-derived spoil that is placed below organic matter-rich topsoil). Reconstruction of the landscape includes designing local watersheds to direct surface water

Fig. 6 Water that drains through spoil from mines is often highly acidic because of the oxidation of sulfur and iron. This water is toxic to plants and aquatic organisms. Acid Mine Drainage at the Minnesota Ridge Mine, South Dakota, United States. This site was remediated in 2001. Photo by Tom Durkin. Reproduced with permission from the South Dakota Department of Environment and Natural Resources, Minerals and Mining Program.

appropriately to higher-order watersheds. It also requires planning for drainage of subsurface water. Installation of wetlands on the site may afford opportunities for long-term treatment of acidic or metal-contaminated water that passes through the reclaimed spoil.

Rates of soil development in reconstructed mine soils are generally slow. Initially, reclaimed mine soils tend to have “AC” horizon sequences, in which incipient topsoil is underlain by unconsolidated layers lacking soil structure or other pedogenic features (Sencindiver and Ammons, 2000; Howard, 2017). The first steps of pedogenesis include physical weathering of coarse rock and clasts and chemical weathering of minerals. These processes can be accelerated where the spoil is affected by acidic drainage or where it is poorly consolidated and allows for rapid movement of air and water. Organic matter accumulates near the surface as newly established plants and their roots grow and decay. The development of pedogenic structure in both surface and subsurface zones depends on the activity of roots, microorganisms, and fauna that gradually return to the soil. The frequency of wet–dry and freeze–thaw cycles will also regulate the formation of peds. In both reclaimed coal mine spoil of the humid-continental climate of eastern United States and in reclaimed limestone mine spoil in tropical southeastern Brazil, recognizable A horizons in the upper 10 cm of have been observed within 5–6 years, and incipient B horizons have been identified after periods of 20 years. Reclaimed mine soils are typically classified as Entisols in the US Soil Taxonomy and as Technosols in the World Reference Base for Soil Resources.

Similar to mining, the extraction of oil and gas from geologic deposits by traditional drilling methods, hydraulic fracturing (fracking), and excavation of oil sands impacts soil properties and soil processes. For example, significant local land disturbance occurs during the construction and use of access roads, pipelines, and well pads. Loss of vegetative cover at the site may lead to increased soil erosion and concomitant increases in suspended sediments and dissolved solids in local streams. Moreover, the leakage from pipelines or storage ponds or direct disposal of fluid wastes can contaminate soil, surface water, and groundwater with salts, metals and metalloids, naturally occurring radioactive materials, and organic additives. Additional effects of the extraction on soils can be either direct or indirect. For example, deep subsurface injections of fluids during hydraulic fracturing operations and injections of liquid waste from oil production have led to increased numbers of earthquakes in some parts of the central United States. To enable recovery of natural gas, groundwater can be first pumped to the surface from deep coal deposits. Although that water may be saline, it has been used to irrigate nearby cropland, leading to increased sodicity and salinity in the affected soils.

Recent extraction methods, coupled with regulatory oversight and remediation guidelines, have helped to reduce environmental degradation near the sites of oil and gas extraction. For example, because of innovations in the drilling technology associated with hydraulic fracturing, several horizontal wells can be drilled from the same well pad, reducing the number of well pads and access

Fig. 7 The Kennecott Flambeau Mine near Ladysmith, Wisconsin, United States was mined for copper, gold, and silver in the 1990s. At the end of mining, the open pit was completely backfilled with spoil material and native vegetation communities were established. The site now includes wetlands, native prairie, woodlands, and nature trails. Photos before mining (1991), during mining (1996), and after restoration (2001) by T-B0 and courtesy of the Kennecott Flambeau Mining Company.

roads and their collective impacts on soils and vegetation. Also, treatment of saline wastewater with gypsum (CaSO_4) and sulfuric acid or simply diluting it with higher quality water before it is used for irrigation may limit the effects of salinity on the stability of soil structure in irrigated fields. Stockpiling of displaced soil during construction of pipelines and roads facilitates the reconstruction and revegetation of soil at the site.

War

War, like mining, may have rapid and long-lasting impacts on soils (Certini et al., 2013). Examples of soil disturbance associated with warfare, preparation for warfare, and associated military operations include (1) deep soil compaction due to occupation by personnel and movement of heavy machinery and armaments, (2) excavation of trenches to limit movement of people, machinery, and weapons across the soil surface, (3) excavation of mass gravesites, (4) contamination with radionuclides from the explosion of nuclear weapons as in Japan during World War II, (5) contamination by radionuclides near sites of the manufacture of nuclear weapons, (6) contamination by fuel spills and storage of hydrocarbons, and (7) mass slope movements induced by the loss of vegetation from intentionally set fires or incendiary bombing.

The United States' war in Vietnam (1965–72) provides several specific examples of the impacts of war on soil properties and processes (Westing and Pfeiffer, 1972). There, it has been estimated that bombs created some 21 million craters between 1965 and 1971, covering more than 50,000 ha (Fig. 8). The explosion of a 2400-kg bomb typically created a hole approximately 10 m in diameter and 5 m deep. Metal fragments from each bomb could be spread over an area of 0.5 ha. Some craters exposed soil horizons of iron oxide accumulation that subsequently irreversibly hardened to petroplinthite. In local areas, soils were also intentionally disturbed by the creation of extensive underground tunnels that were used to move, hide, and store personnel and materiel. Tunnels were constructed in highly weathered Ultisols and Oxisols where the water table allowed excavation between the depths of 1.5 and 20 m below the soil surface. Once exposed to air, iron oxides in the soil hardened, physically stabilizing the tunnels and their associated underground rooms (Olson and Speidel, 2020).

Similarly, programs to clear vegetation in Vietnam altered soil processes. Widespread and concentrated application of herbicides used to defoliate both crops and native forests, as well as bulldozing of vegetation, resulted in extensive soil erosion, loss of organic matter-rich surface horizons, and increased flooding. Native mangrove forests did not return to the drastically disturbed or herbicide-treated lands. More than 50 years after the application of herbicides ended, dioxin, a manufacturing contaminant in the herbicides, remains in the soil and sediments of the countryside and near former military bases, endangering both water supplies and the human food chain (Olson and Morton, 2019). Soils affected by the Vietnam war effectively began a new phase of pedogenesis with new topography, less organic matter, disturbed parent material, and vegetation altered from the previous state of dynamic equilibrium.

In addition to the persistence of war-related changes on soil properties and processes, there may be indirect effects that have a cascading environmental impact caused by displacement of civilian, agrarian populations. In rural Vietnam, soils in bomb craters were contaminated with metal fragments, unexploded ordnance, and residual dioxin. War-related destruction of water-diversion structures has also slowed agricultural and forestry recovery for inhabitants of Vietnam. In response, some farmers have moved to less-productive, marginal land that is more susceptible to erosion. Others have moved to cities, increasing the environmental pressures on urban areas. Thus the impacts of war on soil properties and processes can lead to long-term land-use changes that affect not only soil but also people and cultures who depend on it.

Climate change and soil formation

Soil formation is closely tied to climate, and to the extent that human activities alter local or regional climate variables such as temperature and effective precipitation, soil properties inevitably change also (Horwath and Kuzyakov, 2018; Ruddiman, 2010). At the global scale, climate change is driven by increasing atmospheric concentrations of “greenhouse gases” such as carbon dioxide (CO_2), methane (CH_4), and nitrous oxide (N_2O). As a result, the mean temperature of the Earth’s surface is rising and could increase by approximately 2–4 °C by 2100. Although the local impacts of global warming are difficult to predict with certainty, significant shifts in the mean and seasonal variation of air temperature as well as in the total and seasonal distribution of rainfall are changing natural and agricultural ecosystems. The effects of global increase in temperature are unevenly spread in both space and time. Some of the impacts include: (1) new precipitation patterns in which today’s wet regions become wetter and dry regions become drier; (2) migration northward of boreal and hardwood forests; (3) melting of ice sheets, sea ice, and glaciers, with concomitant rise in sea level that results in salt water intrusion, flooding, and submergence of coastal soils; and (4) melting of permafrost in northern latitudes and oxidation of organic matter now stored in cold-region soils. For example, thawing from temperature increase is shrinking the extent of approximately 11 million square kilometers of Gelisols (about 9% of global land surface), the cold-region soils with permafrost, where an estimated 30% of the world’s soil organic carbon resides (measured to 3-m depth). The release of significant amounts of CO_2 and CH_4 from organic matter-rich Gelisols when permafrost thaws would result in a positive feedback loop between climate warming and soil change.

Human activities over the last 200 years especially, mainly burning of fossil fuels, have thus led to increasingly rapid climate change (Ruddiman, 2010). Both regionally and locally, climate change directly and indirectly impacts soil processes by altering vegetation patterns, encouraging increased water and wind erosion, favoring mass movement, increasing the leaching of nutrients and organic matter through soils, and favoring microbial oxidation of organic matter in surface horizons.

Human-induced climate change is also altering soil by increasing the intensity and extent of fire on the landscape. Fire has always influenced soil formation and properties through mineral weathering, organic matter decomposition, and nutrient cycling. Fire plays key roles in ecosystem functions, and has also been used through human history as a management tool to increase soil fertility and to manage vegetation. In recent years, however, highly destructive “megafires” of unprecedented intensity and magnitude resulting mainly from climate change and fire suppression policy have become common in forest and grassland ecoregions that are most vulnerable to drought and warming such as in the Mediterranean, Australia, and western North America. Such extreme wildfires harm soil health by direct biological sterilization and combustion of organic matter, and indirectly through accelerated erosion following the elimination of protective vegetative cover and the development of water-repellent layers in soils. With increased aridity and temperature, and degraded soils with reduced organic matter and ability to retain and transmit water, compromised ecosystems are unable to recover. Human-induced underground fires in organic soils such as Histosols may burn uncontrolled for years, significantly increasing greenhouse gases.

Although it is difficult to predict how fast soil properties will be altered as a result of global and regional climate change, it is likely that some types of soil horizons will be lost (for example, surface horizons composed entirely of organic matter) and some types will develop where they did not previously exist (for example, spodic horizons under new boreal forests that replace tundra). As human populations adapt agricultural practices to new climate conditions, further changes in soils may be accelerated. For example, salinization may increase due to more extensive irrigation, and landscape instability may become widespread as more forest land is cleared for the production of crops and livestock. Furthermore, patterns of cultivation and grazing will shift with changing climate and weather patterns.

Significance and future of human impacts on soil formation

Soil is a critical, dynamic natural resource and vital component of ecosystems, but one that is often neglected. This is in part because soil lies hidden beneath the surface and so is not as familiar to people as water, plants, or animals. As a natural resource, soil is crucial for food-, fiber-, and fuel-production systems, for construction materials and foundations, for replenishing and maintaining the quality of surface water and groundwater, and for waste processing and containment. Natural variation in pathways of soil formation and soil properties make for a diverse range of suitabilities for different land uses and sensitivities to anthropogenic change. Conservation of soil resources and soil quality is a critical priority globally because soil is fundamentally nonrenewable on a human time scale.

Human activities dictate that soil change is inevitable and necessary. Anthropogenic soil change has a long history (Winiwarter, 2014), but it has increased exponentially in intensity, spatial extent, and rate since the 19th century. Some changes are advantageous and improve soil functionality. However, many soil changes induced by past and present land use have resulted in environmental degradation. In developed and developing nations alike, accelerated erosion, compaction and disruption of structural aggregates, decreased fertility, and contamination by pollutants continue to be sources of serious concern. Because soil serves as a filter, substrate, and reservoir linked to other land, water, and biological resources, degradation is not just detrimental to the soil internally and locally, but it extends to all parts of the larger hydrologic, geologic, and biological systems. Some soils, like plants and animals and the habitats and ecosystems with which they are closely connected, have become endangered and in some cases extinct (Drohan and Farnham, 2006). Soils are a key part of global environmental degradation such as desertification, acid precipitation, and loss of tropical forest ecosystems. Human-altered soil is a significant factor in global environmental change as both a cause and a

consequence of change. For example, oxidation of soil organic matter by cultivation is a source of increased atmospheric CO₂ and climate change, which leads to further soil change. Yet improved management techniques and restoration of soil health provide promise of carbon sequestration in soils and ecosystems.

What can be done to counter the negative impacts of human activities on soils and the environment and to support goals of conservation, soil security, and more sustainable land use (Amundson et al., 2015; McBratney et al., 2014)? Current efforts to document soil biodiversity, assess soil health in a more holistic way, and promote regenerative agricultural practices can help to achieve these goals (Lal, 2020). Improved knowledge of soil formation and soil change is an important component of these efforts. By recognizing more clearly the extent of soil change and understanding its causes, mechanisms, and consequences, the better our chances become to develop and implement management practices that can sustain soil resources and restore damaged land. Traditionally, soil maps have portrayed soils in their relatively original, undisturbed state. However, because of the unprecedented scale of soil change and massive transformation, it is imperative that anthropogenic soil change be documented, monitored, and acted upon to a much greater degree (Tugel et al., 2005). Efforts to deal seriously with the extent and significance of human impact on soil formation and distribution have led to expanded classes of human-altered soils (Bryant and Galbraith, 2003; Soil Survey Staff, 2014) and to a proposal to include Artesols (connotes artifacts) in the US Soil Taxonomy, and the recognition of Anthrosols and Technosols at the highest level in the current international soil classification system (World Reference Base for Soil Resources; IUSS, 2014). Improved knowledge of soil formation processes in relation to natural and human-altered pathways is essential to the restoration of ecosystems and the development of sustainable land use. The future of human society and the Earth we inhabit depend on soil formation processes, and increasingly, on how we respond to the changes human actions cause in soils and the biosphere.

Abstract

Soil characteristics and processes are dynamic and may change distinctly during pedogenesis. Rather rarely, soil evolution occurs only progressively. Phases of stagnation or regression can be observed. Under undisturbed conditions, the soils evolve by showing mostly a humped to exponential function. With time, rates of soil production, erosion, and soil organic matter sequestration strongly decrease. With aeolian additions, this trend is more linear owing to a constant rejuvenation of the soil material. Soil formation is strongly governed by the availability of water and infiltration rate. More recently, the link between soil formation and the Earth's water cycle has become clearer with the recognition that in situ weathering rates are mostly flux-limited.

Key points

- Soil formation can be modeled by a humped, exponential or power law function.
- The trajectories of pedogenesis are often characterized by progressive and regressive phases.
- Organic carbon sequestration rates decrease strongly with increasing pedogenesis.
- Aeolian soils and soil formation in deserts are markedly different.
- Soil production and chemical weathering are primarily limited by water infiltration.
- Threshold response to external stimuli or internal change suddenly and irreversibly affects soil processes.

Introduction

Soil is a transition phase in the continuum of the Earth's surface weathering processes as minerals and rocks alter to more stable chemical states. Understanding the processes and rates of alteration of materials from their original state to phases that are more stable at the Earth's surface is basic to defining and implementing the sustainable use of soils.

The need for such understanding of the chemistry and physics of the solid surface environment is increasing. This is at least partially due to the realization of the impact(s) that human activity has on the global, regional and local cycling of chemical constituents that directly and indirectly affect all kinds of surface weathering processes.

New rock material is exposed to surface weathering whenever a glacier retreats, a landslide descends, a volcano erupts, a sand dune is removed or a lake is drained. Each event marks "time zero" so that the initial state of the resulting soil is defined with respect to the corresponding parent material, topography and climate. In pedology we are interested in the dynamics of soil characteristics and processes and how these change over time. Soil formation and the rates of soil formation/production depend primarily on (i) the original lithology of the parent materials (e.g., highly reactive minerals such as carbonates and sulfates vs. crystalline rocks), (ii) the interaction with vegetation and other organisms, (iii) the rate of supply of fresh regolith through physical weathering and erosion on various geomorphic surfaces, (iv) the age of exposure, and (v) the character of the hydrological system. This harkens back to the fundamental concept of Dokuchaev (1883) and, in an extended form, of Jenny (1941), both cited in Huggett (2021). With respect to the dynamics of soil development, the terms soil production and soil formation are frequently used and require brief explanation: "Soil production" designates the gross production while "soil development (or soil formation)" describes the net effect.

Fig. 1 A conceptual soil evolution model, showing progressive and regressive phases and phases of stagnation compared to the dominant soil evolution pathway (dashed red line) under undisturbed conditions (Johnson and Watson-Stegner 1987, Phillips, 1993; both cited in Huggett, 2021). Threshold effects may accelerate or decelerate soil formation and strong human impacts (tipping point) may drastically increase soil degradation leading to a soil crisis.

- *Soil production*: In general, soil production describes the transformation of the parent material into a soil due to chemical/physical weathering and mineral transformation resulting in the lowering of the bedrock (or parent material)—soil boundary. It can thus be paraphrased as gross regolith production.
- *Soil formation* (or soil development; see e.g., Jenny (1941), Minasny et al. (2008)): Pedogenesis can be progressive or regressive. Progressive pedogenesis includes processes that promote differentiated profiles leading to horizonization (anisotropy), leaching, developmental accretion, and soil deepening (Fig. 1; Minasny et al., 2008) while soil erosion dominates during regressive pedogenesis. Thus, soil formation is the net increase in soil thickness over time that includes the net effect of progressive (accretion) and regressive processes (erosion).

Soils and landscapes are known to form in complex and non-linear ways over thousands of years. Periods of dominantly progressive soil processes (e.g., soil deepening, regolith weathering) alternate with periods of dominantly regressive processes (e.g., erosion) due to rapid and substantial changes in many of the controlling factors of the various weathering processes. Soils can exist only if the rate of soil production is higher than denudation (erosion). Soil formation (F_{Soil}) can be therefore be expressed by

$$F_{\text{Soil}} = P_{\text{Soil}} - D_{\text{Soil}} \quad (1)$$

where P_{Soil} = soil production and D_{Soil} = soil denudation. Progressive phases occur when soil production is greater than soil denudation and regressive phases occur when soil denudation rates are greater than soil production. Denudation (D) consists of the sum of chemical weathering fluxes (W_{Soil}) and physical erosion fluxes (E_{Soil}) with

$$D_{\text{Soil}} = W_{\text{Soil}} + E_{\text{Soil}} \quad (2)$$

Thus, chemical and physical weathering and mineral transformation contribute to progressive soil formation, whereas strong erosion leads to regressive development and thereby to surface lowering and denudation (Raab et al., 2018). Phillips (1993) developed a model that incorporates progressive and retrogressive pedogenesis and related it to soil development (Fig. 1). Phillip's analysis revealed that soil development may be chaotic, with the soil profile state at any time being unique that depends on the interplay of progressive and regressive soil-forming processes (Huggett, 2021). According to Phillips (1993) (cited in Huggett, 2021) soil development can be expressed as

$$\frac{ds}{dt} = \frac{dP}{dt} - \frac{dR}{dt} = c_1 e^{-k_1 s} - c_2 e^{-k_2 s} \quad (3)$$

where s is soil development (degree of alteration and profile development), c_1 is the maximum rate of progressive pedogenesis P , c_2 is the maximum rate of regressive pedogenesis R , k_1 and k_2 are coefficients describing the decrease in P and R rates as soil develops (Huggett, 2021).

Fig. 2 (A) Schematic overview of soil forming (and, schematically, biotic processes giving rise to aggregates) along a slope. The symbol *e* refers to the weathering front and, thus, the interface between bedrock (or parent material) and soil; *h* is the soil thickness. Atmospheric input is given by *A* and the transformation of parent material into soil by *T_{soil}*. The input of organic matter (*O*) and gas output due to decay (*G*) is mediated by biotic processes (schematically drawn in the image magnification, where organic matter is decomposed, mixed with the mineral matrix, and pores are created). (B) Comparison between rates of soil production (alpine and Mediterranean areas; Egli et al., 2018) and erosion. The red circles indicate global catchment-averaged rates (Chile, northern and southeastern Australia, California, Oregon Coast Range). Data from Heimsath AM, DiBiase RA and Whipple KX (2012) Soil production limits and the transition to bedrock-dominated landscapes. *Nature Geoscience* 5: 210–214.

It has been generally acknowledged that soils evolve over time and, under more or less stable topographic conditions, increase their thickness (Fig. 2). Based on a global data compilation, soil production and denudation (erosion) positively correlate to each other (Heimsath et al., 2012; Fig. 2). A high rate of denudation rejuvenates the soils, exposes fresh minerals to the surface and thus increases the rates of weathering.

McFadden (2013) argued that in some regions, such as arid rangelands and deserts, the processes of accretion imbedded in the soil “production” model are not appropriate to explain how the observed soils developed. In these areas, the genesis of soils is controlled by processes associated with a model of *accretionary-inflationary profile* (AIP) development. The soil thickness model was elaborated by Johnson et al. (2005; cited in Huggett, 2021). In principle, the following processes contribute to soil thickness (*T*):

$$T = (W + B) + (A + O + V) - (E + L + C_{\text{surf}} + C_{\text{sub}}) \quad (4)$$

Accretionary processes in the expanded soil thickness model include bedrock weathering (*W*), bioturbation (*B*), sediment accretion (*A*), rate of organic matter accumulation (*O*), and volume expansion (*V*). Removal processes include surficial erosion and mass wasting (*E*), leaching (*L*), and surface consumption by fire, uptake, decay and harvesting (*C_{surf}*), and subsurface removals (*C_{sub}*) by the same processes.

As a consequence of these considerations, the mass balance of a soil is the result of the difference between soil material production from the parent material, aeolian input and erosion (or denudation). For all soils, changes in soil material mass can be expressed by:

$$\frac{\partial(\rho_w h_w)}{\partial t} = \rho_{\text{UA}} Q_{\text{UA}} - \nabla(\rho_w Q_D) = (\rho_r Q_r + \rho_A Q_A + O) - \nabla(\rho_w Q_D + C) = \phi - \nabla q_e - \nabla q_w - \nabla C \quad (5)$$

where ρ = bulk density (*w*: soil; *r*: parent material), h_w = soil material thickness, Q_{UA} = soil material mass production rate per unit area, Q_A = aeolian input contributing to soil formation, Q_D = denudation mass flux rate per unit area, ϕ = soil production rate, q_e = soil erosion rate per unit area, q_w = chemical weathering rate per unit area and C = gain/loss of organic matter.

Due to steep slopes and in many cases extreme climate conditions, mountain soils may experience particularly high rates of erosion and chemical weathering, and consequently, production rates. Soil production and transport play essential roles in controlling the spatial variation of soil depth and therefore hillslope hydrological processes, distribution of vegetation, and soil biological activity.

Soil accretion

Principles

Soil chronosequences are commonly used to analyze the temporal course of pedogenesis. A time-dependent sequence of soils formed on progressively older landscapes is considered a chronosequence, while the quantitative variability of a characteristic along these landscapes is a chronofunction (Bockheim, 1980). Using chronosequences, soil formation or even soil production rates can be

calculated. A time series of soils that have developed under constant environmental conditions is very rarely achieved. In general, soils that started forming at subsequent points in time over the Holocene or Pleistocene may have been under the influence of different climatic conditions for some parts of their lifetime (Zwanzig et al., 2021). Despite efforts to keep all soil forming factors constant except time when establishing soil chronosequences, various differences in vegetation or parent material characteristics, etc., may occur even in the same study area (Zwanzig et al., 2021). Nonetheless, soil chronosequences can provide very useful information about weathering regimes and soil morphogenesis and they have greatly advanced our understanding of short- to long-term landscape processes. Soil development has been successfully correlated to land surface age in several regions, although in some cases such studies were complicated by erosion and sedimentation as well as possible tectonic activity (Sauer et al., 2010). Thus, the study of chronosequences has a long tradition, and both ecologists and soil scientists use the concept of substituting space for time to understand ecosystem and soil evolution.

Soil evolution

Soils form only when accretionary processes exceed denudation rates (Eq. 1). Therefore, soil trajectories must be dominated by progressive processes.

Birkeland (1984) argues that most chronofunctions are fitted best by a power model, but some are fitted better by linear or exponential models. Although problems exist in the purity of the chronosequences because other soil-forming factors are not completely constant, duration of pedogenesis seems to be the most significant factor in explaining the trends. When a regolith cover is lacking, soil production and formation stall at the beginning. As soon as physical weathering starts to break up the rock, chemical weathering increases up to a maximum and then decreases exponentially. This description depicts a ‘humped’ function and was first described by Gilbert (1877; in Riebe et al., 2017). The humped and negative exponential soil production function can be described as follows (Riebe et al., 2017; Fig. 3):

$$P = P_0 e^{-bh} (1 + ch) \quad (6)$$

Here P is the soil production rate, h is soil thickness, and P_0 is the production rate under zero soil thickness. The parameter b is a scaling factor for the decrease in rate of production with increasing h , and c designates the thickness at which soil production is maximized. For $c = 0$, the humped function turns into a negative exponential, with a maximum production rate of P_0 at $h = 0$ (Riebe et al., 2017). Soil production rates attain a maximum at an intermediate soil thickness. Today, it is widely thought that other processes, such as root wedging and animal burrowing, could contribute to humped soil production functions in landscapes.

The exponential phenomenology for the soil production function obscures the connections between solute transport, chemical weathering, C and N sequestration rates, and soil production processes (Hunt and Ghanbarian, 2016). The cause of this difficulty is that chemical weathering and non-Gaussian transport (Hunt and Ghanbarian, 2016) are described using power laws, rather than an exponential phenomenology (see below). It is increasingly recognized that weathering processes and thus soil formation are transport limited, i.e., by the water infiltration rate.

Aeolian influx

Aeolian materials affect soil development in many ways. Aeolian influx is usually considered to be associated with “progressive” soil development (Fig. 1), since new materials are added to the soil that build up the profile thickness. Such external influences can completely alter the “direction” of soil development and are considered to be external threshold effects. Loess and dust deposition occurs worldwide. Both glacial and non-glacial processes produce fine-grained particles that can be transported by the wind (Muhs, 2013). Silt and dust production is caused by glacial grinding, by fluvial comminution, from volcanic activity, by frost shattering, chemical weathering, aeolian abrasion, by salt weathering in desert basins, etc. Silt and dust may then be transported over short to long distances and deposited giving rise to a new substrate for soil formation.

In desert areas with large amounts of aeolian influx, soil development is often cumulative as it is associated with the development of desert pavement forming over continually thickening vesicular A horizons (Fig. 4). Soil profile anisotropy then develops over time within the accumulated materials rather than as a result of a purely bedrock-to-soil transformation as often proposed by a soil “production” model. This contrast is especially noted in the hillslope soils of arid rangelands (McFadden, 2013). McFadden (2013) suggests that the model for soil formation in deserts is ‘markedly different’ from the CLORPT-based A/B/C model of soil development generally attributed to Dokuchaev (1883) and Jenny (1941) and the soil production function model. McFadden (2013) suggests that a model of *accretionary and inflationary profile* (AIP) development (an “upward growth” model) is more appropriate for areas where entrapped dust becomes translocated beneath desert pavement features (Fig. 4).

Over time, as aeolian influx of mineral materials thicken surface horizons (unless surface erosion is greater than the rate of influx), the aeolian deposits change the soil physical/chemical characteristics by adding new materials of various mineralogies to the grain size distribution. The physical changes may then affect a cascade of physical and chemical processes. With proceeding soil evolution, the predominantly silt-sized particles are translocated deeper into soil profiles through water percolation and freeze-front activity. These conditions are often seen in coarse-textured arctic and alpine soils. The additional materials change the infiltration characteristics of subsurface horizons, so that under unsaturated conditions, the textural difference(s) caused by the accumulation of silt-sized particles may temporarily retard deeper infiltration. Under seasonally saturated conditions with a high gravitational head,

Fig. 4 Conceptual model of soil development dominated by accretion (according to McFadden, 2013; Muhs, 2013).

Fig. 5 Carbonate accumulation in granitic soils (outwash terraces) over time due to dust input. From Dahms D and Egli M (2016) Carbonate and elemental accumulation rates in arid soils of mid-to-late Pleistocene outwash terraces, southeastern Wind River Range, Wyoming, USA. *Chemical Geology* 446: 147–162.

however, water is “flushed” deeper into the profile. When the water table is seasonally high, water may be translocated upward by capillary action into horizons that ordinarily are unsaturated. Over time, these seasonally saturated conditions contribute to the formation of “redoximorphic” features in deeper soil horizons. Since the addition of the aeolian parent material is ultimately responsible here, the textural change that creates the conditions for redox features is considered to be an “external” pedogenic threshold (Muhs, 1984; see below).

The purely accretionary model of McFadden often does not strictly apply and, particularly in less dry regions, aeolian input is admixed into the parent material or existing soil (see the model given in Muhs, 2013). Aeolian influx may change soil characteristics through changes in weathering pathways. Minerals supplied through aeolian influx will become actively involved in common weathering reactions (solution/hydrolysis/hydration/redox) that introduce ‘new’ soluble minerals to subsurface horizons (e.g., CaCO_3 , CaSO_4 , etc.). If these new minerals were absent from the original parent material complex, their presence constitutes a threshold, after which other processes may occur that would not have previously occurred. Examples of such a process are seen in the U.S. western mountains where carbonate dust is commonly added to granitic parent materials of alpine soils (Dahms and Egli, 2016; Fig. 5). As soil moisture dissolves the dust, it moves into the subsurface where it retards the translocation of clays and impedes the development of argillic horizons over time.

Reheis (1990; cited in Dahms and Egli, 2016) reported that carbonate-rich aeolian dust affects the major-element geochemistry of soils on a chronosequence of granitic outwash terraces in Wyoming in a manner that varies according to moisture conditions. The B horizons of the moist soils developed at logarithmic rates while those of the most arid soil developed at linear rates. The variation is apparently due to differences in leaching rates and the addition of aeolian silt, clay, CaCO_3 and gypsum, which act to increase the water-holding capacity in the moist-area profiles. In a similar manner, the clay minerals of the B horizons varied according to moist–dry conditions. Vermiculite, illite-smectite and smectite form in B horizons of the moist chronosequence, while smectite and palygorskite form in the dry B horizons. Amorphous clays appear to be the main clays in the aeolian complex (rather than crystalline forms), which are only later transformed into crystalline clays in these profiles. In other parts of the world, e.g., Middle Europe, soils in mountainous areas are also strongly influenced by aeolian silt. On slopes, cover beds have often developed. Waroszewski et al. (2018) showed that many mountainous soils have an aeolian contribution with a different geologic origin. The incorporation of aeolian silt is the main agent in initiating and stimulating clay translocation and the formation of an argic horizon within mixed zones or just below the boundary between the silt mantle and coarse/fine basal strata.

Organic matter

If the evolution of soils is not disturbed too much by erosion and accumulation processes, then organic matter stocks and rates of accumulation of carbon and nitrogen depend greatly on the age of the surface (or soil, respectively). In a review of Holocene chronosequence studies in a variety of ecosystems, Schlesinger (1990; in Egli et al., 2012) found a much higher and more variable rate of C accumulation in relatively young soils. In Alpine environments, soils developed on silicate parent material can accumulate up to $\sim 40 \text{ kg organic C m}^{-2}$, with frequent values between 15 and 25 kg C m^{-2} (Egli et al., 2012). Within about 500 years, the rates of carbon accumulation decrease markedly to very low values (Fig. 6). Based on an investigation of 10 glacier forelands distributed on four continents, Khedim et al. (2021) found that the rate of SOM accumulation in topsoils is accelerated by higher temperatures

Fig. 6 Compilation of org. C (A) and N (B) stocks as a function of soil age and calculated rates of sequestration over time for C (C) and N (D) for alpine areas worldwide. Data from Egli M, Favilli F, Krebs R, Pichler B and Dahms D (2012) Soil organic carbon and nitrogen accumulation rates in cold and alpine environments over 1 Ma. *Geoderma* 183–184: 109–123.

during the warmest quarter, suggesting that climate and time are key factors of SOM build-up during the initial stages of topsoil development after glacier retreat. The stability of SOM decreases with soil age at all sites, indicating that SOM storage is dominated by the accumulation of labile SOM during the first centuries of soil development, suggesting plant carbon inputs to soil (SOM depleted in nitrogen, enriched in hydrogen and in aromatic carbon). A steady state of the amounts of stable organic C and N compounds is often reached within about 1000 years (Egli et al., 2012).

Erosion

Evolution of erosion rates in natural soils

The surface of the continental Earth is constantly reworked at different scales of time and space by weathering and erosion. Natural rates of soil formation counteract soil erosion and can be used as a basis for setting tolerable rates of soil erosion (Verheijen et al., 2009).

Since soil properties change over time, one has to expect that soil erosion rates also change in parallel. At the beginning of soil formation, e.g., due to glacier melt and exposure of fresh material, the vegetation cover is often scarce, which promotes soil erosion. Such areas are prone to strong erosion. With time, vegetation can establish and increasingly covers the surface and therefore minimizes the erosive power of rainfall (Fig. 7).

In the mid-European Alps, the erosion rates are strongly reduced after about 3 kyr of soil formation, whereas under drier conditions (e.g., Wind River Range of the Rocky Mountains, US) it may take longer until slopes stabilize. Depending on the relief and vegetation development, it takes up to at least 10 ka to reach soil stability (Musso et al., 2020).

Several recent studies have attempted to compare erosion rates over various periods of time in order to estimate rates of different geomorphic processes. Qualitative or quantitative estimates of erosion rates over different time-scales have been reported for river sediment yields, lake and marine sedimentation (Bajard et al., 2017) or for speleothem growth rates. Raab et al. (2018) and Mariotti et al. (2021) report that (soil) erosion and denudation rates have varied considerably in the Mediterranean and European Alps over the last ca. 100 kyr. High-resolution cores collected in the Mediterranean Sea provided a near-continuous reconstruction of

Fig. 7 Temporal evolution of erosion rates in two proglacial areas of the Alps (Musso et al., 2020).

denudation in the Southern Alps since 75 kyr ago (ka). These high-resolution palaeo-denudation records were compared with well-constrained climatic variations over the last glacial cycle. Mariotti et al. (2021) concluded that denudation rates were approximately twice as great as during the Last Glacial Maximum LGM (26.5–19 ka). Raab et al. (2018) showed that denudation rates were about five times higher in the Mediterranean directly after the LGM and reached values of about $\sim 150\text{--}200 \text{ t km}^{-2} \text{ year}^{-1}$ (compared to $30 \text{ t km}^{-2} \text{ year}^{-1}$ before the LGM and during Holocene). Bajard et al. (2017) showed that the erosion rates in an Alpine catchment were mostly very low during the Holocene (about $1 \text{ t km}^{-2} \text{ year}^{-1}$), but increased sharply during the last ~ 3 kyr.

Present-day and past erosion rates

In many agricultural landscapes, soil erosion rates are an order of magnitude higher than possible soil production rates. As shown by Bajard et al. (2017) and Raab et al. (2018) and several others, erosion rates strongly increased after humans started to use soils more intensively. Often, erosion rates increased even more than one order of magnitude compared to natural rates leading to strong soil degradation. It has become obvious that soil erosion in the Anthropocene mainly occurs as a consequence of a combination of natural and human-induced soil erosion processes. In an increasing number of case studies anthropogenic soil erosion processes have become dominant (Poesen, 2018). The first signs of increased erosion due to human impact apparently occurred in the Bronze age and became increasingly obvious about 2 ka BP (Bajard et al., 2017). Taking steps to preserve the quality and quantity of global soil resources should require no justification (Poesen, 2018).

Thresholds in soil genesis

Soil properties sometimes change suddenly and irreversibly in a threshold response to external stimuli or internal change in soil processes (Chadwick and Chorover, 2001). The concept of the “threshold” was not used explicitly for studies of soil genesis until recently. Muhs (1984) noted that, unlike traditional geomorphic studies of landscape development, studies of soil genesis have not explicitly used the threshold concept. Yaalon (1971) presented examples of research that applied the concept, but they refer to it only indirectly as, respectively, a “metastable state”, an “environmental” threshold or a change in one of the “state” factors (Jenny, 1941).

Two types of thresholds are normally recognized: *Extrinsic* and *Intrinsic*. Extrinsic thresholds involve alterations that are associated with changes in external variables that are outside the immediate soil system to explain variations or changes in soil development/genesis. Examples of external thresholds that change the trajectory of soil evolution might be changes in climate, temperature/precipitation gradient, parent material or vegetation succession. These are easily seen in alpine environments where, with similar parent materials, soils develop from Inceptisols -to- Mollisols -to- Spodosols. These developments occur because various of these gradients are crossed with increasing altitude that cause changes in organic matter content, water percolation and associated changes in soil geochemistry. Dixon et al. (2016) show that soil chemical changes occur rapidly across a narrow portion of a rainfall gradient, indicating that water availability creates thresholds for soil weathering. In a temperate to cool-temperate climate zone (New Zealand Alps), Dixon et al. (2016) measured soil elemental geochemistry along a large precipitation gradient ($400\text{--}4700 \text{ mm year}^{-1}$). They found evidence of an important pedogenic threshold that coincided with a mean annual precipitation of $\sim 800 \text{ mm year}^{-1}$, which was associated with cation weathering and release, and the rapid mobilization of trivalent metallic ions.

Intrinsic thresholds are those that can be crossed only after a prior change in a physical/chemical property alters the direction of soil genesis *in the absence of environmental change* (Muhs, 1984). The accumulation of authigenic clays in argillic horizons that eventually decreases internal drainage conditions (Yaalon, 1971; Muhs, 1984) is an example of an intrinsic pedogenic threshold. In such a case the valence state of Fe can be changed from ferric to ferrous. This change may then trigger a cascade of geochemical processes beginning with the replacement of ferrous Fe in dioctahedral-smectite that subsequently decreases the content of dithionite-extractable Fe over time. Bockheim (1980) observed Fe in B horizons to reach a maximum value and then to decrease over time.

A primary suite of chemical reactions in soil involves the production of acids by biodecay or atmospheric input and their depletion through the weathering of minerals (Chadwick and Chorover, 2001). Soil development can be characterized as a long-term acid–base reaction in which acids react with bases in the form of rock minerals to form secondary minerals and soil solution alkalinity. Depending on the buffering capacity and type of buffer range, there is little change in the soil pH when acids are added because weathering mechanisms are able to buffer these acids.

Additional examples of intrinsic thresholds where no change in external variables is involved include the impediment/movement of clays in the presence of Ca^{++} or Na^{++} (Muhs, 1984). The flocculating effect of Ca^{++} may be cancelled by sufficient leaching of free carbonates, thus allowing clays to begin to move. Likewise, in soils developing on parent materials rich in marine shales, as an appropriate amount of Na^{++} is released by weathering of the parent material, it enhances the ability of clay to move and rapidly accumulate. However, this has a limit which becomes another intrinsic threshold; once clays accumulate to an extent that pore spaces become too small to allow adequate percolation, little clay movement can occur subsequently (Muhs, 1984).

Physical explanations and consequences for soils and landscape

Weathering, soil formation, vegetation succession and its decay and integration into the soil are all processes that are interconnected and driven by (solar) energy and moisture availability. Soil formation and vegetation growth are both processes with significant impact on global C cycling, although the primary influences differ at widely varying time scales. Individual organisms, populations, community distributions and ecosystem composition and function strongly depend on water availability, the energy balance and organic matter. The organisms supply the CO_2 for the weathering and soil formation processes. Together with the pore separation (particle size) that defines the fractal dimensionality of a soil system, the water flow rate determines the rate of soil formation (Hunt and Ghanbarian, 2016).

Recent modeling and comparisons with field results showed that soil formation by chemical weathering, either from bedrock or unconsolidated material, is more often limited by solute transport than by reaction kinetics. Predicting what drives the transition from ‘non-soil’ to a soil-mantled landscape (or from bedrock to a “developed” soil mantle) is, therefore, a significant challenge for models of landscape evolution and for “critical zone” studies. If predictions for the rates of soil formation and vegetation growth, at both regional and global scales, can be made accurately, effects of future climate change on alpine systems can be assessed more reliably.

Although precipitation is abundant in many regions, the availability and flux of water through the soil is the prime factor that controls weathering intensity. This understanding derives from the percolation theory, that both vegetation growth and soil formation processes are proportional to the water fluxes remaining after direct evaporation processes are excluded, including interception (e.g., Hunt and Ghanbarian, 2016). Thus, the rate of reaction is proportional to the water throughflow within the Earth’s skin (i.e., the soil or regolith), and quantifying the partitioning of water at the terrestrial surface–atmosphere interface becomes key to understanding rates of weathering around the world (Egli et al., 2018).

Water fluxes in soils depend on evapotranspiration, overland flow, subsurface flow and vertical percolation. These partitions of water and in particular the soil infiltration rates often vary greatly as a function of topography. Polar-facing sites are usually characterized by lower evapotranspiration rates and thus have higher rates of infiltration than equatorial-facing slopes (Fig. 8; Pelletier et al., 2018). As a consequence, soil characteristics are often developed better at polar-facing sites where more water infiltrates and so, chemical weathering is less limiting (Figs. 8 and 9). The conceptual model of Pelletier et al. (2018) can be related to weathering rates, soil formation, soil biology, organic matter and wood decomposition. They all indicate that infiltration rates and thus water predominantly control the rate of reactions (Fig. 8; Hunt and Ghanbarian, 2016). This system, however, is valid only to a certain point, from which temperature, and thus a higher thermal gradient, becomes more important. This holds for very cold environments in which lower temperatures on polar-facing slopes limit vegetation cover and reverse many of the feedbacks associated with the water-limited case (Pelletier et al., 2018).

Hunt and Ghanbarian (2016) proposed upper bounds for three processes described by scaling relationships: soil depths, natural vegetation, and crop heights, each as a power of time. The bounds are related to maximum water flow rates. The general scaling relationship can be represented as

$$x = x_0 \left(\frac{t}{t_0} \right)^P \quad (7)$$

with the primary distinction among these cases being the value of the exponent P . For both natural vegetation and intensively managed crops, the variable x represents the height or root radial extent; for soils, x represents depth. The variable t represents the

Fig. 8 Conceptual models for a water-limited soil-mantled case. Soils are less developed on equator-facing hillslopes, due to the limiting water storage potential. Adapted from Pelletier JD, Barron-Gafford GA, Guitérrez-Jurado H, Hinckley E-LS, Istanbuluoglu E, McGuire LA, Niu G-Y, Poulos MJ, Rasmussen C, Richardson P, Swetnam TL and Tucker GE (2018) Which way do you lean? Using slope aspect variations to understand critical zone processes and feedbacks. *Earth Surface Processes and Landforms* 43: 1133–1154; photograph: Altai mountains, Russia.

Fig. 9 Relative element losses due to weathering and chemical leaching in the Alps where $\tau_{j,w}$ denotes the open-system mass transport function, i the immobile element, $C_{i,p}$ (g kg^{-1}) is the concentration of element j in the unweathered parent material, and $C_{j,w}$ is the concentration of element j in the weathered product (g kg^{-1}). Chemical losses are distinctly higher at north-facing sites (moister conditions) than at south-facing sites.

time since germination for plant growth; for soil depth, it is the time since exposure at the surface. The spatial scale, x_0 , relates to a grain or pore (or plant xylem) diameter, and x_0/t_0 is the water flow rate, v_0 , underlying the particular process.

It has been shown that, under the assumption that chemical weathering is limited by solute transport (and thus water flow into the soil), the process of soil production may be predictable (Hunt and Ghanbarian, 2016; Fig. 10). Such predictions appear successful when applying percolation theory for solute transport in porous media. The percolation theory can be used when the medium is highly disordered and chemical weathering in situ is transport-limited (Hunt and Ghanbarian, 2016). Variations in soil depth and vegetation characteristics with topography appear to be best understood when we consider the effects of aspect on rates of erosion and the effect(s) of water supply and energy balance on soil production (Fig. 10).

Soil depth represents the integration of soil production and denudation (Fig. 2). Denudation (D) is the sum of erosion (E) and chemical leaching (W): $D = W + E$.

Temporal differentiation of Eq. (1) for soil depth generates the soil production function:

$$\frac{dx}{dt} = R - E(t) = \frac{1}{1.87} \frac{x_0}{t_0} \left(\frac{t}{t_0} \right)^{-0.87} - E(t) = \frac{1}{1.87} \frac{I(t)}{\phi} \left(\frac{x}{x_0} \right)^{-0.87} - E(t) \quad (8)$$

Fig. 10 Time trends of modeled (using the percolation theory, Eq. 8) and measured soil thickness for distinct geographic regions, (A) alpine soils, (B) Mediterranean soils. In alpine soils, mineral weathering seems to be kinetically limited until about 1 kyr.

with $I(t)/\phi$ as the net infiltration rate that varies, like E , over time. From this equation it is evident that solute transport through soil (similar to erosion of soil matrix) limits the formation of soils. Solute transport limitations reflect the necessity for flowing water to bring reagents to (chiefly CO_2), and to remove reaction products from, the reaction zone (the bottom soil boundary), preventing equilibration. Thus, depending on local/regional climate forcing, soil depth implicitly reflects slope processes in terms of erosional and biological processes (Figs. 2, 7 and 8).

Under steady-state conditions, soil production and rates of soil erosion are equal. Soil production is proportional to the rate of water infiltration, meaning that processes such as evaporation and interception reduce the water available for replacing soil lost by erosion, thus also placing a limit on the rate of erosion (Fig. 9). At longer time scales, carbon and nitrogen sequestration rates appear to have the same time-dependence as rates of soil formation (Hunt and Ghanbarian, 2016). Similarly, steady-state in biologic processes, presumed relevant for a given climatic regime and for near steady-state soil conditions, would imply an equality of production and consumption of carbon stocks in the soil. The higher rates of decay on north-facing slopes can be explained by the greater moisture content. Under conditions of climate or land-use change, however, steady-state conditions will be disrupted, leading to rates of soil erosion (and soil carbon depletion rates), for example, that are larger than rates of soil production (and carbon sequestration). Such effects are also expected to be aspect-dependent, with the most pronounced impacts on equator-facing slopes because water infiltration is hypothesized to be lower and erosion rates higher compared to north-facing sites giving rise to shallower soils. At high altitudes (above the treeline), we expect a reversal of these processes.

Transport limitation and *kinetic limitation* are often processes that determine the speed of silicate weathering. A transport-limited weathering regime exists when the supply of water, inorganic and organic acids and ligands are large relative to the supply of silicate (West et al., 2005). The supply of fresh minerals limits the weathering rates. Old and flat topographies are typically in this category. A *kinetic* limitation is then given when the main control on chemical weathering ω depends on the kinetic rate of mineral dissolution W , the supply of material (e.g., by erosion) e , and the time t available for reaction (West et al., 2005)

$$\omega = W \cdot e \cdot t \quad (9)$$

Mineral dissolution (W) depends on environmental conditions such as temperature and runoff (or precipitation). The rate of weathering of a mineral or rock decreases with the time the mineral spends in the weathering environment (West et al., 2005). Apparently, young surfaces or surfaces exhibiting a high erosion rate (leading to a continuous rejuvenation of the surface and soils) are in this category (Fig. 9).

The percolation theory model therefore fails when simulating soil formation on young surfaces (Fig. 9). This seems to be the case up to about 100 years, but sometimes up to 1000 or more years of soil formation (Fig. 9; Egli et al., 2018). During early soil formation, chemical weathering is more limited by reaction kinetics than by solute transport. Thereafter, solute transport seems dominant. Thus, the reaction rate is proportional to the water throughflow within the Earth's skin, and quantification of the partitioning of the water at the interface between the terrestrial surface and the atmosphere becomes key to understanding the rates of weathering around the world (Hunt and Ghanbarian, 2016).

Conclusion and outlook

Soil formation and production rates in general tend to decrease distinctly over time and can be best modeled using a humped, an exponential function or a power model. Often undisturbed conditions are not encountered and soil formation can even be regressive. The trajectories are influenced by a number of internal and external processes (among which also anthropogenic

activities can be mentioned). Soil formation in deserts is “markedly different” and rather tends towards a linear development. As soil chronosequences are crucial to the study of soil genesis and since chronosequence studies are based on the concept of *time* as an independent (i.e., external) variable, the passage of time can be seen to enable any number of internal thresholds. That is, it takes time for silicate weathering to produce enough authigenic clays to then be organized in sufficient concentration to decrease the movement of soil water; it takes *time* for a soil solution to remove enough Ca^{++} to allow clays to move and accumulate in argillic horizons. Thus, the use of soil chronosequences is important to studies of soil genesis and landscape evolution, since only by seeing the effect of time the presence and the effect(s) of internal thresholds can be illuminated.

Although it seems obvious that the availability of water and its transport through the soil determines the rate and trajectories of soil formation, a number of questions remain open. It is still not fully clear why the rates of weathering of minerals measured in the field are several orders of magnitude less than those obtained from laboratory experiments. According to Fig. 10, a phase of kinetic limitation is detectable in alpine soils, but not in Mediterranean soils (with the available datasets). Therefore, it would be interesting to know under which conditions a kinetic control is dominant and when exactly the change into transport limitation occurs. Given the fact that soil production rates (Fig. 2) vary over 3–4 orders of magnitude (Hunt and Ghanbarian, 2016), the soils have a robust tendency to be about 1-m deep in temperate to boreal climates, with the topsoil and the typical rooting depth about one third of that (Hunt and Ghanbarian, 2016; Egli et al., 2018). Aeolian, (semi) desert soils seem to exhibit a linear evolution trend with time. If and when a quasi-steady state will be established is so far uncertain. The characteristics of threshold in soil evolution are known, however not their influence on the rate of soil production and organic matter sequestration.

Weathering of silicate rocks removes CO_2 from atmosphere. With rising levels of atmospheric CO_2 , the understanding of rates of weathering is increasingly important—also when related to enhanced weathering of silicates as a removal technology by adding powdered silicate rock to agricultural soils (Andrews and Taylor, 2019)—to estimate the true ability of weathering to sequester carbon.

Abstract

There is little doubt that anthropogenic activities have led to increasing atmospheric carbon dioxide (CO₂) concentrations, global temperature increases, changes in precipitation regimes and more frequent occurrence of extreme events. These global change effects alter soil properties and their biogeochemical functioning. In this chapter, I will present the global impacts and likelihood of these change and their influence on soil functioning, biogeochemical cycling and ecosystem services in different environments. Feedbacks between the effects of climate change and soil will be presented and soil-based strategies for climate change mitigation and adaptation will be discussed.

Key points

- Increasing CO₂ concentrations, increasing temperature and altered precipitation regime affect organic and mineral soil properties, biogeochemical cycling and provision of ecosystem services.
- These effects may be direct and or indirect through their influence on vegetation and plant growth.
- Extreme events affect soil degradation processes through increasing soil erosion, salinization, desertification and frequency of fire. Their impact on organic and mineral soils is contrasting.
- Feedbacks between soil degradation and climate change occur through CO₂ uptake and release from soils.
- Sequestration of organic and inorganic carbon in soils may be options for climate change mitigation and adaptation. They require large scale implementation through region- specific strategies.

Introduction

Soils form through the interaction of five factors, including (1) parent material, (2) relief or topography, (3) organisms (including humans), (4) climate, and (5) time. The nature of this interaction varies in the different regions of the world, resulting globally in several thousand soil subtypes and transition phases. Soil formation is a long process and consequently it takes thousands of years for a soil to form, while in comparison global changes in the anthropocene have occurred only recently after the beginning of industrialization. Even rapid changes in any of the soil-forming factors following global changes will affect directly and indirectly biogeochemical cycling and functioning of soils, with important implications for their development and use. As a result, human activity impacts soil formation through perturbations of several earth system processes at the planetary scale. Global changes affecting soil are related to the increasing atmospheric CO₂ concentrations leading to climate change, loss of biosphere integrity including genetic and functional biodiversity, and perturbations of the biochemical flows by massive use of N (nitrogen) and P (phosphorus) fertilizers for agricultural production.

This chapter focuses on the increasing atmospheric CO₂ concentrations inducing global changes in climatic conditions. These include temperature and moisture, which may influence soils and the ecosystem services they provide. Depending on their nature, soils are likely to respond in various ways to climate change. For example increasing global temperatures may lead to increased (micro-) biological activity and change microbial community composition, thereby affecting soil organic matter (SOM) storage and biogeochemical cycling. Temperature and precipitation changes also alter the rates of mineral weathering. Moreover, extreme

Fig. 1 Global change pressures on soils and the reasons for requiring adaptation.

events, such as drought and flooding are likely to increase under climate change and may not only have various effects on soil biota and biogeochemical cycling, but could also influence soil salinity due to irrigation measures (Corwin, 2021) and rates of soil erosion (Routschek et al., 2014). Other climate change impacts include rising sea levels, which may affect soils in coastal areas (Corwin, 2021) and increasing frequency and size of wildfires (Keyser and Westerling, 2019), which may disturb soils under forest ecosystems. All these climate change effects will most probably alter the functioning of natural as well as managed ecosystems. However, the effects of climate change will not operate in isolation, as perturbations of earth system processes may interact. To secure ecosystem service provision, food security and to build the bioeconomy of the 21st century under global changes, system adaption will be necessary (Fig. 1).

While climate change may thus affect a number of soil properties, soils are also responding to climate change through the release and uptake of CO₂ and other greenhouse gases. These processes occur as positive and negative feedback mechanisms following increasing temperatures and/or after changes in landuse and management. In the past, these alterations mainly led to the release of CO₂, N₂O (nitrous oxide) and CH₄ (methane) to the atmosphere following intensive agricultural practices, which favored SOM decomposition leading to a carbon loss of more than 100 Gt since the beginning of industrialization (Sanderman et al., 2017). However, it was recognized that sustainably managed soils may be carbon sinks and they were thus cited as a nature-based solution to mitigate greenhouse gas emissions (Bossio et al., 2020), thereby fighting climate change.

This chapter introduces the main climate change predictions and their likely effects on soil properties and their consequences for soil functioning and biogeochemical cycling. The possibility of mitigating these effects by sustainable management of soils to contribute to climate change mitigation, adaptation and food security will also be discussed. Organic and mineral soils will be distinguished, as their response to climate change may be substantially different (Rumpel, 2019).

Climate change predictions

Estimates of global climate change are continually being revised as models are being improved and new data are collected. The current main sources of information to inform on the likely extent of climate change are the Sixth Assessment Reports of the Intergovernmental Panel on Climate Change. The latest report of working group one on the physical science bases, which integrates scientific knowledge based on 14,000 publications, concluded that human influence has warmed the climate at a rate that is unprecedented in at least the last 2000 years. The increase in global surface temperature relative to 1850–1900 (IPCC, 2021) was +1.1 °C in 2020. As a consequence, northern ice masses are melting leading to sea level rise and permafrost thawing. In addition, with warmer air temperatures the atmosphere can hold more water and more water will be evaporated and returned to land with heavier and more frequent precipitation. Global warming consequently leads to extreme events such as heavier rainfall and flooding, the intensification of dry seasons in some regions with more frequent and more intense heat waves, droughts and more frequent fire events. Some of the projected environmental changes and their likelihood are presented in Table 1. These events driven by climate change have already been recorded in every inhabited region of the world and there is medium to high confidence in the human contribution to the observed changes (IPCC, 2021). As a result, the Sixth Assessment Reports include assessment of climate change mitigation and adaptation options.

Soil is addressed in the IPCC's special report on land and climate change, which was released in 2019. This report indicated that warming over land has occurred at a faster rate than the global mean and that these warmer temperatures and associated changing patterns of precipitation have altered the start and end of the growing seasons, and reduced the availability of freshwater (IPCC, 2019). These changes affect soil through their impact on vegetation and this is likely to increase in the future. However, there is also considerable confidence in options for land based mitigation and adaptation involving soil through sustainable land management practices that could both reduce emissions and increase carbon uptake. These options have co-benefits in the form of enhanced crop productivity, plant nutrient status and/or biodiversity.

Table 1 Projected climate change induced alterations of the global environment.

<i>Changes in environmental conditions</i>	<i>Confidence in projections</i>
Global temperatures will continue to increase until 2050	High confidence
Global water cycle will continue to intensify with temperature increase	High confidence
Global area experiencing increases or decreases in seasonal precipitation will increase	Medium confidence
Drought and or flooding events will intensify	High confidence
Monsoon precipitation is projected to increase	High confidence
With increasing CO ₂ emissions, sink efficiency on land and ocean decreases	High confidence
Mountain and polar glaciers will continue melting for decades or centuries	Very high confidence
Global mean sea level will continue to rise over the 21st century	Virtually certain

Impact on soil properties and biogeochemical cycling

Increased CO₂ concentrations and associated temperature may affect physicochemical soil properties and in particular weathering processes. Indeed, rising atmospheric CO₂ concentration was found to increase soil acidity, although carbonic acid is only a weak proton source. This effect may be even stronger under nitrogen fertilizer application. Thus increased atmospheric CO₂ concentrations may enhance rates of chemical weathering directly because of increased dissolution of CO₂ in soil water, which leads to the weathering of silica, depending on the lithology, ambient temperature and moisture conditions. Indirectly weathering may be affected by climate change through its effect on plant and soil (micro-)organisms as they are strongly involved in these processes (Rosenstock et al., 2019). Weathering processes, may lead to the removal of CO₂ from the atmosphere through pedogenic carbonate formation as a negative feedback mechanism. Therefore, it has been suggested that artificial acceleration of this carbon sink by the distribution of pulverized silicate rocks across the Earth's surface, especially in tropical regions, where weathering rates are high, could help to offset anthropogenic CO₂ emissions (Taylor et al., 2016). However, the authors also indicate that this solution has major barriers due to costs, social acceptance and unanticipated consequences.

In addition, the increase of CO₂ concentrations and associated higher air temperatures have strong impacts on soils and their properties through their effects on the soil–plant continuum. Alteration of both parameters influences vegetation growth and plant physiology. As a result, increasing atmospheric CO₂ concentrations were hypothesized to lead to greater carbon input into soil following more intensive photosynthesis, thereby increasing the terrestrial carbon sink. However, evidence from field experiments and observations is contradictory. Consequently, other factors, such as temperature, nutrient and or water availability may also play a role and strongly alter the plants' response to elevated CO₂. Plants may respond by several mechanisms to changes in the physicochemical properties of their environment including those of resource allocation and stoichiometry with consequences for soil processes and soil carbon residence times (Walker et al., 2021). A recent literature review indicated that greater plant input belowground may be compensated for by increased soil organic carbon (SOC) turnover. Indeed, high plant-derived C input may affect microbial biomass and its activity, metabolism and respiration. It may also induce positive priming of SOC and nutrient pools. A recent study concluded that following elevated CO₂, pool sizes may be unaltered while process rates could be increased thereby accelerating soil biogeochemical cycling and organic matter turnover (Kuzakov et al., 2019).

Soil microbial activity, such as growth and enzyme production, depends on temperature. Much research interest has been given to the temperature sensitivity of SOM decomposition, which is critical for forecasting the fate of soil (organic) carbon under a warming climate. In theory, under ideal conditions with non-limiting substrate availability, SOM decomposition follows Arrhenius kinetics and increases exponentially with temperature (Arrhenius, 1889). In these cases, the relative temperature sensitivity increases with chemical recalcitrance of the organic substrate and the stable, slow cycling SOM pool will be more vulnerable than the fast cycling pool (Davidson and Janssens, 2006). This might be the case for organic soils of peatlands, which formed under oxygen deficiency resulting from high water tables. Such soils are present on only 3% of the land area mainly in the boreal and temperate regions. Nevertheless, they are important contributors to the global carbon budget as they store 21% of the global SOC stocks (Leifeld and Menichetti, 2018).

In mineral soils, with less than 20% organic carbon in the surface layer, the situation is different as the residence times of SOM are less controlled by its chemical structure than by its location within the soil matrix. Under such conditions, the temperature sensitivity of SOM decomposition may be determined by the nature of physicochemical protection mechanisms rather than substrate properties (Von Lützow and Kögel-Knabner, 2009). Evidence from recent field studies suggested that physical protection of SOM constrains the temperature sensitivity of its decomposition. Consequently, temperature sensitivity of SOM decomposition in mineral soils was found to decrease with increasing SOM stability, which is in direct contrast to the Arrhenius theory (Moinet et al., 2020).

More than half of the organic carbon in soil is often stored below the topsoil and possibly also affected by global warming, as the world's soils are assumed to warm by 4.5 + 1.1 °C down to 1 m by the end of the 21st century under the Representative Concentration Pathway (RCP) 8.5 (IPCC, 2014). Therefore, recently attention has been paid to biogeochemical processes occurring in whole soil profiles subjected to warming. A better understanding of the response of the deep soil carbon reservoir to warming would probably contribute to a decrease in the large uncertainties in model predictions of soil responses to warming. A recent study

showed that warming by 4 °C of profiles of forest mineral soil down to 100 cm augmented CO₂ emissions from all depths increasing annual soil respiration by 34–37% (Hicks Pries et al., 2017). This is considerably more than observed in previous *in situ* studies taking into account only the surface soil. Similar temperature sensitivities were recorded at all soil depths and related to the degradation of decadal-aged SOC. In the forest soil, this warming thus induced an increase in decomposition that led to the loss of subsoil organic carbon and nitrogen stocks and a concomitant increase in topsoil (0–20 cm) SOC stocks (Soong et al., 2021).

Soils of the permafrost regions are likely to be strongly affected by global warming due to thawing. The unique pedogenic processes in these regions on the one hand accumulated large organic carbon stocks and permafrost soils account for approximately 50% of the global SOC pool (Hugelius et al., 2014). The accumulation of organic matter in permafrost-affected soils occurs in the active layer due to their high moisture content and low temperatures, which affect decomposition (Ping et al., 2015). Warming of these soils will lead to changes in their hydrology and microbial functioning. A recent study indicated large SOC losses from high carbon soils affected by permafrost not only as CO₂ but also through lateral hydrological export (Plaza et al., 2019). However, the vulnerability of the accumulated SOC stocks to climate change will depend on several parameters, including its form and protection mechanisms, vegetation establishment and the soil microbial consortium (Ping et al., 2015). On the other hand, vast permafrost regions have mineral soils with sparsely distributed vegetation and shallow soils without prior accumulation of thick organic layers. In these regions, warming leads to changes in soil chemical, physical and (micro-)biological properties, which may favor plant life and soil development (Doetterl et al., 2021). In particular, rates of (bio-)chemical weathering of mineral surfaces may be enhanced under warmer and wetter conditions (Hall et al., 2002) and global warming may therefore accelerate soil formation through increasing the kinetics of chemical reactions and vegetation establishment. These processes could lead to soil carbon sequestration thereby partly compensating for carbon loss from thawing organic permafrost layers (Doetterl et al., 2021).

In addition to temperature, moisture availability is a major factor determining microbial substrate access, SOM decomposition and soil biogeochemical cycling at several scales. As climate change leads to extreme climatic events such as drought and flooding, fluctuations in water availability will strongly influence microbial community composition and activity with effects on soil physicochemical properties and its organic constituents.

Drought, for example, has direct negative consequences for microbial activity and substrate access by causing osmotic stress through increased salt concentrations in the soil solution and consequently ionic strength. This can alter chemical environments at the pore scale and influence the sorption and desorption of stabilized organic molecules at mineral surfaces. Drought leads to reduced access to nutrients and organic matter by limiting substrate diffusion within the soil pore network. It also has impacts on leaching losses of elements and rates of mineral weathering (Schlesinger and Bernhardt, 2013). On the other hand, flooding may lead to anaerobic conditions directly affecting the microbial community composition. It also has consequences for the soils' redox potential and the chemical form of mineral soil constituents such as Fe (iron) and Al (aluminium), which in reduced forms may be less able to stabilize organic matter and may adversely affect plant growth. To investigate the changes in soil processes and biogeochemical cycling *in situ* long-term experiments that generate empirical data in multiple environments and climatic contexts are necessary. Long-term monitoring sites are also necessary to benchmark model projections. Improved biogeochemical models are needed to increase confidence in the magnitude of projected soil–climate feedbacks. Model improvement should be done by including recent advances in mechanistic understanding of soil biogeochemical cycling (Bradford et al., 2016).

Impact on soil functions and ecosystem services derived from soil

Soils are fundamental to land-based ecosystems and, in association with climate, govern the nature and distribution of the world's ecosystems. They are multifunctional natural bodies providing water, nutrients, and habitat for a number of organisms. Soil functions can be influenced by management and may be altered by climate change. Although most ecosystems are naturally variable with time and adapt reasonably well to small climatic fluctuations, changes to soils as a result of climate change are likely to influence their function and this will also be reflected in a change in ecosystems and their services (Fig. 2). The form the change will take depends much on the degree of climate change, and the possibility of adaptation through management.

The most recognized function of soils is their production function and the implications it has for feeding the global population. Indeed, production of food and other commodities relies over 90% on soils and food security of a growing population puts pressure on soils, which are already degraded to a large extent (FAO and ITPS, 2015). Climate change effects on the physical, chemical, and biological properties of soils alter their nutrient recycling function. This impacts the soil biogeochemical cycles and biodiversity with major implications for their fertility and thus their production function (Smith et al., 2015). Soil properties are also important in controlling the fate and behavior of water once it reaches the surface. Therefore, related soil functions likely to be influenced by climate change are water storage and filtration. Consequently, global warming and resulting changes in the precipitation regime may affect the ability of crops to reach maturity and in extreme cases may lead to crop failure.

There are likely to be major changes to the distribution of water under a changed climate. Reductions in amounts of soil water may be compensated for by irrigation, but scarcity of water may preclude the use of (fresh) water for irrigation. Reduced vegetation growth, heavy rainfall events and use of water with high electrolyte content may increase the risk of land degradation, whether in the form of soil erosion, desertification, and or salinization (see below). Current predictions of climate change indicate a likely shift in agricultural zones, requiring a movement of populations, new farming methods, development of new skills, or some combination of these. Soil management will be central to adapting to these new conditions.

Fig. 2 Effects of global changes on soil processes, biogeochemical cycling and ecosystem services.

Soil also plays an important part as a medium supporting buildings and other infrastructure, and in protecting our archeological heritage. Current infrastructure will almost certainly need to change to meet the new climatic conditions.

Finally, climate change concerns associated with the amounts of greenhouse gases in the atmosphere have focused on the soils' function to store carbon, and their ability to act as a source and or sink for CO₂ and other greenhouse gases. The fact that the soil can act as both a source and sink for several greenhouse gases, e.g., CO₂, N₂O, and CH₄, has recently become an important issue in the quest to reduce the impacts of climate change (see below).

Impact on land-degradation processes

Land degradation is already one of the major problems affecting the world's population. The estimated global extent of the degraded area ranges between <10 to >60 million km² (Gibbs and Salmon, 2015). Currently the estimated amount of soil eroded annually ranges between 35.9 and 75 Pg (Borrelli et al., 2013), desertification affected 270 million ha of global drylands between 1982 and 2015, and salinization is affecting some 833 million hectares of global land area (FAO, 2021). Land degradation through damage to the soil is a serious problem and its causes are often complex and interwoven. Severe damage has already been done to the world's soils, and the impact of climate change needs to be considered in addition to existing pressures on the land. It is difficult to separate these various effects, and their cumulative impact on soils is often greater than a simple summation. Land degradation processes are affecting a large percentage of the global population of emerging economies vulnerable to climate change. Despite the fact that there is confidence that land degradation processes are likely to be exacerbated with ongoing climate change and act as a positive feedback (Fig. 3), there are large uncertainties concerning its extent, severity and links to the climate change (IPCC, 2019).

Soil erosion

Soil erosion is a natural phenomenon, which is controlled by biophysical factors and strongly influenced by land use and especially vegetation cover and agricultural activities. The main erosion process leading to important soil loss in most global environments is hydrological erosion. As global precipitation and especially rainfall amount, intensity and spatiotemporal distribution changes and extreme events, such as heavy rainfall may increase under climate change (IPCC, 2021), soil loss through water erosion may be directly affected (Li and Fang, 2016). There are strong region-specific differences in these impacts, with high and mid-latitude wet regions being most affected. However, hydrological erosion following heavy rainfall events may also increase in dryland areas with sparse vegetation. Moreover, soil erosion may be affected indirectly by climate change through its effects on vegetation and changing landuse practices. Indeed, climate change through its multiple consequences for plant growth and risks including a greater abundance of pests and extreme climatic events leading to crop failure and vegetation dieback may lead to bare soils, which consequently are more exposed to erosion events (Li and Fang, 2016). Moreover, landuse practices are likely to change thereby

Fig. 3 Relationship between climate change induced extreme events and land degradation.

affecting rates of soil erosion. Another indirect effect leading to increased rates of erosion following climate change is increasing soil salinity (see below). High salt content leads to clay dispersion, which may consequently make the soil more prone to be exported by water erosion. The combination of all of these factors increases uncertainty of the impact of climate change on soil erosion.

Quantification of global change effects on soil erosion and their inclusion into earth system models is complex. As a result, the database of erosion responses to climate change is sparse. In fact, depending on the region, soil type and management, effects of climate change may be positive, negative or non-existing (Li and Fang, 2016). However, using a global database average erosion rates in most cultivated soils were already found to exceed the tolerable rate of $1 \text{ t ha}^{-1} \text{ year}^{-1}$ (García-Ruiz et al., 2015). Climate change is likely to exacerbate soil erosion in regions where it is already severe (Li and Fang, 2016). Therefore, soil protection measures are required including afforestation, conservative tillage regimes and the maintenance of permanent soil cover (Routschek et al., 2014).

Desertification

Desertification is the process of ecological degradation by which economically productive land becomes less productive, in some cases leading to the development of a desert-like landscape. It occurs mainly in hyperarid, arid, semiarid, and subhumid climatic zones, ranging from precipitation: potential evapotranspiration indices (P: PET) of less than 0.05 to 0.70 (IPCC, 2019). The area of land occupied by these four zones in which true or induced deserts can occur is 47% of the planet. With the increased temperatures and evaporation due to climate change, this percentage could increase. There is a huge literature on the nature and causes of desertification, some of which indicates that human impacts arising from overgrazing, overcultivation, and deforestation are primarily responsible for the process, while others lay the blame on the impact of extended droughts over the last few decades. In reality, desertification is likely to be due to a combination of drought and mismanagement of land, particularly where there is a lack of harmony between land use and management on the one hand and prevailing climate on the other. Disentangling the roles of the different factors was identified as a key knowledge gap by the three UN conventions (UNCCD, UNFCCC and UNCBD).

Salinization

The accumulation of salts in soils can negatively affect soil properties and processes. It can lead to degradation of soil structure, decline in porosity, and increase in bulk density, and adversely affect nutrient dynamics by impeding nutrient-holding capacity. It leads to a decline in productivity and can cause land to become unsuitable for agricultural production. Soil salinity is already a major global problem in Australia, Africa, Latin America, and the Near and Middle East (FAO, 2021). It is typically found in areas where evaporation exceeds precipitation and salts accumulate in soil. In the USA alone, some 50 million hectares of cropland and

pasture are affected by salinity, and the area of land so affected is growing by some 10% annually. Salinization is likely to be prevalent in three situations:

- Coastal zones. In these situations salinity is likely to depend primarily on the sea level and its tidal, seasonal, and long-term fluctuations. Given that the global mean sea level is projected to rise by 15–30 cm regardless of emission reductions until the middle of the century (IPCC, 2021), there is likely to be a territorial extension of coastal salinity under the direct and indirect effects of saline seawater. Impacts are likely to include flooding of coastal plains by saline seawater, including low-lying coastal fringes, marshlands and swamps, deltas and estuaries of some of the world's largest rivers, increase in storm tides affecting areas several meters in elevation around the coast, with penetration of saline and brackish water inland, and rapid erosion of coastlines. For example, the soils of the Bangladesh delta, the world's biggest delta, are strongly threatened by salt water intrusion following sea level rise affecting the livelihood of 160 million people.
- Continental salt transport and salt accumulation processes. There are three principal mechanisms of this form of salinization: salt accumulation, seepage, and wind deposition. Salinization by salt accumulation happens when leaching is reduced and salt accumulates at or near the surface. It can also occur when salt is leached into a perched water table and the water moves through the landscape to areas of lower elevation, where the water evaporates, leaving the salts. Given suitably exposed deposits of salts, wind erosion can transfer the salts elsewhere in the landscape. Global salinization hotspots are South America, southern and western Australia, Mexico, southwest United States, and South Africa (Hassani et al., 2021).
- Management induced salinization. Agricultural management, in particular the excessive use of mineral fertilizers and saline irrigation water, can lead to salt accumulation. For example, potassium is applied to soils as potash in the form of KCl (potassium chloride) and has a strong effect on salinization as Cl^- remains in soil pore water or is leached to groundwater (Buvaneshwari et al., 2020). Poor irrigation water quality and or the reuse of degraded water (e.g., drainage water or municipal waste water) are another source for salt addition to agricultural soil. Climate change, especially in dry areas or under drought conditions can lead to an increase of degraded water reuse (Corwin, 2021).

All of these causes of salinity are likely to be enhanced with climate change. Zones subject to rising temperatures during the summer will experience more evapotranspiration and aridity and thus higher concentrations of salt in the soil solution. There may also be enhanced capillary rise from shallow water tables with the potential to carry salt into the overlying soil horizons. Where climate change leads to increasing wetness as well as temperature, there will be a reduction in the concentration of salts in the salt solution. However, where periodic drying is also involved, capillary upward transport of salts can take place from shallow groundwater to overlying soil horizons.

Given the predictions for climate change, the extent of salt-affected soils is likely to increase globally, although there may be a small improvement to a few of the existing saline areas of the world.

Fire

The frequency of fire will increase following climate change due to the occurrence of drought and heatwaves, leading especially in forests to the accumulation of high fuel loads. Mineral soils have poor heat conductivity and fire usually has little effect on their properties. In contrast, fires have strong effects on the degradation of organic soils, which are lost with combustion. Organic soils occur in large extents under boreal forests, constituting the carbon sink recorded for these environments. A recent study showed that shortening of the fire return intervals following climate change may lead to legacy carbon loss, thereby transforming boreal forests from a carbon sink into a carbon source (Walker et al., 2019).

Soil-based climate change mitigation and adaptation options

Options for soil-based climate change mitigation are focused on soil carbon sequestration. Carbon accumulation in soils may occur in organic and also inorganic forms. While SOC sequestration refers to biological processes involving plants and carbon capture through photosynthesis, accumulation of inorganic carbon may occur through silicate weathering and involve pedogenic carbonate formation.

In terms of SOC sequestration, it has been suggested that increasing the global SOC stocks by just a few per mil could effectively counteract the increasing atmospheric CO_2 concentrations (Balesdent and Arrouays, 1999). Because SOC sequestration, a so-called nature based solution for climate change mitigation, has many advantages and is technically ready to be implemented without requiring spare land, it has received a lot of policy attention at the highest level (Rumpel et al., 2020). It led to the launch of the 4 per 1000 initiative at the 21st conference of parties of the United Nations Framework convention for Climate Change, a global initiative with the aim to increase soil carbon to mitigate and adapt to climate change and to increase food security. All three goals may be met because SOC sequestration comes with co-benefits for many ecosystem services and may greatly contribute toward achieving several sustainable development goals. However, quantitative evidence about the relation of soil carbon increases and specific soil properties is scarce although it is well accepted that organic matter enrichment in soil increases its quality. Moreover, SOC

sequestration may have trade offs, such as other greenhouse gas emissions and or water and nutrient requirements (Rumpel et al., 2020).

Therefore, increasing standing SOC stocks should be achieved by the implementation of sustainable soil management practices, which reduce environmental effects such as greenhouse gas emissions, and at the same time ameliorate soil properties, ultimately benefitting soil productivity. Such practices are known, and include best management practices such as permanent soil cover, conservation tillage, organic fertilizer use, conservative fertilization practices, improved grazing management and agroforestry (Paustian et al., 2016). On the other hand, inorganic carbon sequestration in soils may be favored by specific technologies, such as enhanced weathering, and may be able to decrease atmospheric CO₂ concentrations (see above).

It has been pointed out that region-specific soil carbon sequestration practices need to be implemented at scale by millions of farmers to have a global impact as a climate change mitigation strategy (Amelung et al., 2020). To take into consideration the requirements of all actors involved including policy makers, practitioners, scientists, NGOs, businesses and the general public, multistakeholder collaboration is necessary (Rumpel et al., 2018).

Conclusion, summary, outlook

Increasing atmospheric CO₂ has led to changes in global temperature and precipitation regimes. These alterations lead to increasing frequency of extreme events such as drought, heat waves and flooding. All of these changes affect organic and mineral constituents and alter soil properties, biogeochemical cycling and ecosystem services. Their effects may be direct, for example enhanced weathering rates and microbial activity. Others are indirect through plant activity and vegetation growth. Climate change effects are region specific. Whereas in arid climates, salinization and desertification may lead to land degradation as a result of climate change, areas with high precipitation may show increases in soil loss through water erosion. Increased temperatures may increase rates of mineral weathering thereby increasing soil inorganic carbon sequestration. They may also lead to salinization of coastal areas due to sea level rise. Because of the negative consequences of climate change for soil functioning and ecosystem services, especially in vulnerable regions, a global effort is needed to reduce atmospheric CO₂ concentrations. This would need immediate and aggressive emission reduction and negative emission technologies such as SOC sequestration, which if implemented at scale may contribute to combatting climate change while providing many co-benefits because of its positive effect on soil quality.

Abstract

Major primary minerals in soils include feldspars, quartz, micas, and olivines, amphiboles and pyroxenes as accessory minerals. Weathering of these minerals serves as a template for various secondary minerals and to supply elements for the crystallization of secondary minerals in soil environments. Primary minerals are the source of many essential plant nutrients and also provide pH buffering capacity to soils. The weatherability of primary minerals in soils depends on their structural (e.g., points of weakness in the structure) and chemical properties (e.g., presence of Fe²⁺ iron), and environmental conditions. The structure and composition of common primary minerals and their weathering products in soils are described in this chapter.

Key points

- Feldspars, quartz, and micas are major primary minerals in soils.
- Olivines, pyroxenes and amphiboles are accessory minerals.
- The weathering of primary minerals produces important secondary minerals in soils.
- Several essential nutrients are released from the weathering of primary minerals.
- Primary minerals contribute to soil pH buffering capacity and some easily weatherable minerals such as forsterite has potential to contribute to carbon sequestration in soils

Introduction

Primary minerals are formed at elevated temperatures and inherited from igneous and metamorphic rocks, sometimes through a sedimentary cycle. These minerals have not been altered chemically in soils since their crystallization and occur as residuals of weathering processes. In most soils, primary minerals exist in the sand and silt fractions, however, they may be present in the clay fraction of weakly weathered soils. Commonly, primary minerals are minor constituents of the clay fraction of most agricultural soils. The weathering of primary minerals is an important process for the global hydrogeochemical cycling of elements. The process is equally vital in soils, because it releases many essential plant nutrients, such as calcium (Ca), magnesium (Mg), potassium (K), phosphorus (P), iron (Fe), manganese (Mn) and boron (B). The dissolution of minerals and subsequent release of elements determines the chemical composition of soil, soil solutions and terrestrial ecosystems.

Primary minerals are the main source of base cations and their weathering buffer pH and neutralize acid input in the soil. The weathering of primary silicate minerals consumes carbon dioxide (CO₂) through the generation of bicarbonate alkalinity in stream water. In the last few years there has been an increased focus on the potential use of primary minerals such as forsterite to accelerate CO₂ sequestration in the soil to mitigate climate change (Schuiling and Krijgsman, 2006; Köhler et al., 2010).

Fig. 1 Abundance of rocks, minerals and elements in the Earth's crust (rocks and minerals data from Ronov and Yaroshevsky, 1969; and element composition from Bowen, 1979).

Primary minerals in soils are derived from their parent materials, such as rocks, river-borne sediment (alluvium), wind-borne sediment (eolian), hillslope sediment (colluvium), lakebed sediment (lacustrine), materials moved by glacial advance and retreat (glacial till), and volcanic ash. The main source of most unconsolidated soil parent materials is one of the rocks. The abundance of rocks, minerals and elements in the Earth's crust is given in Fig. 1. Igneous and metamorphic rocks represent over 92% (on volume basis) of the crust. The clays, shales and to a lesser extent carbonates and sands are the main constituents in the thin veneer of sediments present at the Earth's surface (Wyllie, 1971). Feldspars and quartz are the dominant minerals constituting 63% (on volume basis) of the crust, whereas pyroxenes, amphiboles and olivines comprise 19% and micas 5%. Other minor constituents in the crust include 4.6% clay minerals (including chlorite), 2.0% Ca/Mg carbonates, 1.5% magnetite (and titanomagnetite) and 4.9% other minerals. Oxygen (O), silicon (Si) and aluminum (Al) are three most abundant elements, constituting 47.7, 27.7 and 8.2%, respectively (on weight basis) of the crust. Other elements present in significant amounts are Fe, Ca, Mg, sodium (Na) and K with an average concentration of 4.6, 4.1, 2.3, 2.3 and 2.1%, respectively.

Similar to their abundance in the Earth's crust, feldspars and quartz are the most abundant primary minerals in soils. Both feldspars and quartz are tectosilicates, with a continuous three-dimensional framework of tetrahedra. Quartz is essentially pure SiO_2 , that contains tetrahedra formed by Si and O only, and it is the main form of free silica in soils. Feldspars are anhydrous aluminosilicates in which both Si and Al tetrahedra share all four O atoms with neighboring tetrahedra. Feldspars contain varying amounts of Na, K, and Ca, and occasionally of other cations such as barium (Ba), which balance the negative charge resulting from the substitution of Al^{3+} for Si^{4+} in their structure.

Feldspars occur in virtually all sediments and soils in quantities that vary with the nature of the parent materials and stage of weathering. The weathering of feldspars is an important terrestrial geochemical process. Feldspars are an important source of the plant nutrients K and Ca; they play a substantial role in overall K dynamics in soils.

Micas are 2:1 phyllosilicates with tightly held, non-hydrated, interlayer cations (mostly K) balancing a high layer charge. They are largely of primary origin, occur extensively, and serve as precursors for expansible 2:1 phyllosilicates such as vermiculites and smectites in soil environments. Micas are often present in soils as components of particles that have been only partially transformed to expansible 2:1 minerals through inter-stratification with the other minerals or the formation of mica cores that are surrounded by expanded zones. Micas are important reservoirs of K for plants in soils. The K-supplying power of a soil depends to a large extent on the nature and amount of micas and their dynamics of K release.

Olivines, pyroxenes, and amphiboles are important accessory primary minerals that occur in small but significant amounts. Olivines are olive-green nesosilicates in which Mg and Fe^{2+} are octahedrally coordinated by O atoms. Pyroxenes and amphiboles,

which are inosilicates, are ferromagnesian minerals with single- and double-chain structures of linked silica tetrahedra, respectively. The variety of isomorphous substitution in olivines, pyroxenes, and amphiboles and their relative ease of weathering make them excellent source minerals for Ca, Mg, and trace elements in soils.

Silica

Silica is a chemical term or expression for silicon dioxide (SiO_2) and is often used to describe a range of structures and properties. Silica occurs in nature in at least 15 polymorphs including α -quartz, β -quartz, α -cristobalite, β -cristobalite, α -tridymite, β -tridymite, coesite, stishovite, moganite, keatite, lechatelierite (silica glass), cryptocrystalline silica (chalcedony) and opal (Deer et al., 1992; Heaney, 1994; Guthrie and Heaney, 1995; Götze et al., 2021). Some of the silica polymorphs are metastable and amorphous.

Important properties of common forms of silica are presented in Table 1. Quartz is the most abundant of the silica polymorphs in soil environments. Disordered cristobalite commonly occurs in soils, but tridymite is rare and usually associated with siliceous volcanic rocks. Coesite, stishovite, and lechatelierite, which are formed at high pressures, are rare polymorphic forms in soils. Opal is a generic term for hydrated and amorphous silica, is of biogenic origin, and although minor it is a ubiquitous constituent of soils.

Quartz

Quartz occurs as two polymorphs – α -quartz (low quartz) and β -quartz (high quartz). The β -quartz is only stable at temperatures greater than about 573 °C. Below this temperature it converts to α -quartz, which is stable under surface conditions, therefore, only α -quartz (from here on quartz) occurs in soil. Quartz is one of the last minerals to crystallize from magma. Therefore, it is formed under conditions closer to those present on the Earth's surface than minerals crystallized earlier (at higher temperatures), which contributes to its high thermodynamic stability. Dense packing of tetrahedra in the crystal structure and high activation energy required to alter the Si—O—Si bond are the main factors that contribute to the strong stability of quartz compared to other silica polymorphs. Quartz is in almost all soils and often represents the major portion of all sand and silt fractions. It is also a significant component of the coarse clay fraction of most soils.

The structure of quartz can be visualized as a spiral network of silica tetrahedra about the Z-axis (Fig. 2A). Each tetrahedron is repeated in the network by a rotation of 120° and a translation of one-third about the Z-axis. The tetrahedra are linked to form a hexagonal structure in quartz. The silica tetrahedron of quartz is almost symmetrical and has a Si—O distance of 0.161 nm. The Si—O bond is approximately equally ionic and covalent in nature. The compact structure of quartz suggests that there is limited

Table 1 Some properties of silica minerals found in soil environments.

Mineral Group and name	Formula unit	Crystal system and unit cell	Specific gravity (Mg m^{-3})	Major X-ray diffraction peaks (nm) and intensity (%) in parentheses	Features and presence in soil
α -Quartz	SiO_2	Trigonal $a = 0.4913 \text{ nm}$ $c = 0.5404 \text{ nm}$ $Z = 3$	2.65	0.426 (35), 0.334 (100), 0.246 (12), 0.228 (12), 0.182 (17)	Colorless, white or variable black, purple, green with impurities. Ubiquitous in all soil types, often constitutes major portions in the sand and silt size fractions.
Cristobalite	SiO_2	Trigonal $a = 0.497 \text{ nm}$ $c = 0.692 \text{ nm}$ $Z = 4$	2.33	0.404–0.411 (100), 0.313–0.318 (12), 0.283–0.285 (14), 0.248–0.250 (20)	Colorless, white or yellowish. Occurs in volcanic rocks and co-exist with tridymite.
Tridymite	SiO_2	Orthorhombic $a = 0.504 \text{ nm}$ $b = 0.874 \text{ nm}$ $c = 0.824 \text{ nm}$ $Z = 8$	2.26	0.430–0.433 (90), 0.409–0.411 (100), 0.380–0.382 (50), 0.296–0.298 (25)	Colorless or white. Typically occurs in acid volcanic rocks and abundant in rhyolitic tuffs.
Opal-CT (cristobalite/tridymite)	$\text{SiO}_2 \cdot n\text{H}_2\text{O}$	About 40% non-crystalline structures mixed with crystalline ones related to tridymite.	2.20–2.38	~0.430 (30–40), 0.404–0.411 (100), 0.313–0.318 (12), 0.283–0.285 (14), 0.248–0.250 (20)	Varied, cryptocrystalline blades aggregated into lepispheres that gives color and translucency. Commonly associated with volcanic deposits.
Opal-A (amorphous)	$\text{SiO}_2 \cdot n\text{H}_2\text{O}$		1.50–2.30	Diffuse, broad peak centered at ~0.41 nm	Opaque, opal-A in soils is of biogenic (organic) origin.

The data from Drees et al. (1989), Deer et al. (1992), and Fröhlich (2020).

Fig. 2 The structures of low quartz (α -SiO₂) showing spiral network of Si—O₄ tetrahedra. (A) the structure projected along the Z-axis, each tetrahedron is repeated in the network by a rotation of 120° and the linked tetrahedra form a hexagonal structure in quartz. (B) the intertwined chains when projected parallel to the Z-axis show open channels that are wide enough to accommodate cations such as Al³⁺ and Na⁺.

opportunity for the incorporation of impurity elements, and these usually occur in traces to very minor amounts (Wilson, 2020). However, Fig. 2B shows that the structure is characterized by channels running parallel to the Z-axis, which are wide enough to accommodate other cations either interstitially or as substituents. Aluminum is the most abundant impurity in natural quartz, with concentrations ranging from <13 to 15,000 mg kg⁻¹ (Smith and Steele, 1984). Its presence in quartz relates to its common occurrence in the Earth's crust and the similar ionic radii of Si⁴⁺ and Al³⁺ (Götze, 2009 in Götze et al., 2021). Trace amounts of Ti⁴⁺ (titanium) and Fe³⁺, with comparably large ionic radii, may also occur in marginal parts of quartz crystals. Other monovalent cations, such as H⁺ (hydrogen), Li⁺ (lithium), Na⁺, K⁺, Cu⁺ (copper) or Ag⁺ (silver) can be incorporated in interstitial positions, sometimes acting as charge-compensating ions typically maintaining electrical neutrality. Lithium is frequently incorporated into the quartz structure, whereas Na and K may be hosted by fluid inclusions (Gotze et al., 2004 in Götze et al., 2021). Smith and Steele (1984) observed a range for Na from 9 to 1420 mg kg⁻¹ and for K from 3 to 290 mg kg⁻¹. Plots of the contents of Na + K against Al + Fe showed a 1:1 correspondence (Graetsch et al., 1987).

Solubility of silica minerals

The dissolution of silica in water can be described as follows:

where s and aq represent solid and aqueous phases.

The solubility of silica minerals decreases as a function of increasing packing density of the silica tetrahedra and long-range crystal order. Solubility of quartz at ambient temperatures and neutral pH is commonly 3–7 mg Si L⁻¹, which is much lower than that of amorphous silica (50–60 mg Si L⁻¹). Freshly ground quartz commonly shows abnormally high solubility (37 mg Si L⁻¹).

Fig. 3 SEM images of quartz grains showing (A) distinctive etched steps in the Eg (eluviated or bleached) horizon, and (B) deeply etched pits and linear trenches in the B/C horizon of from a peaty gleyed Spodosol developed on fluvio-glacial sands in north-east Scotland. (C) quartz grains showing intensive etching and (D) etched and disintegrating grains from the Cg (strong gleying) horizon of an imperfectly drained iron Spodosol developed on granitic material. From Wilson MJ (2020) Dissolution and formation of quartz in soil environments: A review. *Soil Science Annual* 71(2): 99–110.

This has been attributed to the formation of a disrupted surface layer, which is believed to be amorphous or microcrystalline. These solubility determinations were made using bulk methods so that the dissolution mechanisms were deduced indirectly. Since the 1980s, however, emphasis has been on the processes, such as development of etch pits at structural dislocations and defects on the grain surfaces, which might have a major control on the overall dissolution kinetics of the mineral (Wilson, 2020). Many researchers have observed abundant etch pitting of quartz where significant dissolution has occurred in the upper part of the saprolite, which was related to undersaturation of solute silica with respect to quartz solubility in the pore water. There is a critical concentration of dissolved silica in the external solution, above which etch pits will not form or form at a reduced rate. However, Wilson (2020) observed extensive corrosion and etching of quartz at all depths within soil profiles from north-east Scotland (Fig. 3), which could have been inherited from the effects of former weathering cycles.

The dissolution of quartz in soils is a function of temperature, pH, and particle size. It increases with increasing temperature and the rate of dissolution also increases with decrease in particle size, i.e., increasing specific surface area. With respect to pH, the minimum rate of dissolution at 25 °C ($10^{-12.7}$ mol quartz $\text{m}^{-2} \text{s}^{-1}$) occurs in the pH range 4–6, which is close to the point of zero charge of quartz (Brantley, 2005). The rate of dissolution increases linearly under both acid and alkaline conditions, with the rate being $10^{-12.0}$ mol quartz $\text{m}^{-2} \text{s}^{-1}$ at pH 2 and $10^{-11.0}$ mol quartz $\text{m}^{-2} \text{s}^{-1}$ at pH 10, indicating that quartz is more soluble under alkaline conditions.

In addition, the concentrations of alkali and alkaline-earth cations, organic acids and Al and Fe species in the external solution also affect the dissolution of quartz. The increased rate of dissolution of quartz in aqueous solutions containing small concentrations of common alkali and alkaline-earth cations (such as Na^+ , K^+ , Ca^{2+} and Mg^{2+}) has been attributed to increased rates of solvent exchange at the mineral–solution interface and rupture of Si—O bonds (Dove and Nix, 1997; Dove and Han, 2007; Dewan et al., 2013). The enhanced dissolution of quartz by organic acids has been suggested to be caused by the effective complexation and mobilization of silica, which decreases the activity of dissolved silicic acid and leads to a far-from equilibrium system. The dissolved species of Al and Fe have been shown to decrease the solubility of quartz, perhaps by forming coatings on quartz surfaces.

Silica as an indicator of soil parent material

Oxygen-isotope composition of minerals is a useful tool for determining the genesis and history of soil parent materials. The oxygen isotope composition of quartz depends on the temperature of formation, with delta values ($\delta^{18}\text{O}$) decreasing as the temperature of formation increases. The delta value ($\delta^{18}\text{O}$) is calculated as follows:

$$\delta^{18}\text{O} = \left[\frac{(\delta^{18}\text{O} - \delta^{16}\text{O})_{\text{sample}}}{(\delta^{18}\text{O} - \delta^{16}\text{O})_{\text{SMOW}}} - 1 \right] \times 1000,$$

where SMOW is standard mean ocean water.

Quartz in igneous rocks has $\delta^{18}\text{O}$ values in the order of 8–13‰, whereas quartz from metamorphic rocks has somewhat higher $\delta^{18}\text{O}$ values, with a wider range that results from varying degrees of metamorphism. Oxygen–isotope ratios of quartz in shales range from 15 to 24‰; the ratios of quartz in sandstones range from 10 to 16‰. Silica minerals, such as cherts, diatoms, plant opal, which are formed at ambient temperatures have considerably higher $\delta^{18}\text{O}$ values ranging up to 35‰ (Allègre, 2008). The intermediate values of sedimentary deposits are attributed to the mixed origins of sediments. Delta values of quartz from soils range from 9 to 30‰, which are generally similar to those of sedimentary rocks. The large value ($\sim 30\text{‰}$) suggests that quartz may have formed in the soil as a secondary mineral (Drees et al. (1989). There is some evidence in the literature that supports this at ambient temperatures in soils (Drees et al., 1989; Wilson, 2020).

Quartz is exceedingly resistant to O-isotope exchange; therefore, its isotopic composition in soils, dusts, and sediments has been used as an indicator of provenance. The main use of isotopic composition of quartz in pedologic studies has been for identification of eolian additions to soils.

Feldspars

Feldspars comprise 595 g kg^{-1} of igneous rock, 300 g kg^{-1} of shale, and 115 g kg^{-1} of sandstone on average. Many metamorphic rocks also contain large amounts of feldspars. Therefore, feldspars are present in virtually all sediments and soils; their quantities vary with the nature of parent material and the extent of weathering of the parent material. Feldspars play a substantial role in the overall dynamics of macronutrients K and Ca in soils.

The structure of feldspars is a three-dimensional framework of corner-sharing SiO_4 and AlO_4 tetrahedra, with sufficient opening in the framework to accommodate K, Na, Ca, or Ba to maintain electroneutrality. In the structure of the framework, four-membered rings of tetrahedra are the basic units. Chains of four-membered rings of tetrahedra are parallel to the X-axis and cross-linked to adjacent parallel chains by shared O atoms (Fig. 4). One zigzag chain is formed by superimposing four-membered rings of tetrahedra that share some of their vertices to form new, four-membered rings. The remaining vertices form cross-links between

Fig. 4 The structure of microcline feldspar projected along the (001) plane. Silicon and Al tetrahedra are shown in light blue and green colors, respectively, the corners of tetrahedra represent O, and the bluish-green color spheres represent K.

Fig. 5 Ternary diagram illustrating composition and nomenclature of feldspars in the orthoclase–albite–anorthite – names based on their chemical compositions, i.e., relative amounts of K, Na, and Ca, respectively. The points of the triangle are so-called ‘end member’ compositions. From Smith JV (1974) *Feldspar minerals: I. Crystal Structure and Physical Properties*. Berlin: Springer-Verlag.

chains. The repeat periodicity along the chain, i.e., the *a*-dimension of the unit-cell is 0.856 nm in the microcline structure (Fig. 4). The *a*-dimension (along the *X* axis) of different feldspars varies from 0.81 to 0.86 nm.

Feldspars represent solid-solutions between three end members orthoclase (potassium feldspar, $K(AlSi_3O_8)$), albite (sodium feldspar, $Na(AlSi_3O_8)$) and anorthite (calcium feldspar, $Ca(Al_2Si_2O_8)$) as shown in Fig. 5 (Smith, 1974). Albite and anorthite form a completely miscible series called plagioclase. The plagioclase feldspars are arbitrarily divided into six minerals based on their mol (%) proportion of albite (Ab) and anorthite (An) (Fig. 5): albite ($Ab_{100} - Ab_{90}An_{10}$), oligoclase ($Ab_{90}An_{10} - Ab_{70}An_{30}$), andesine ($Ab_{70}An_{30} - Ab_{50}An_{50}$), labradorite ($Ab_{50}An_{50} - Ab_{30}An_{70}$), bytownite ($Ab_{30}An_{70} - Ab_{10}An_{90}$), and anorthite ($Ab_{10}An_{90} - Ab_0An_{100}$). These boundaries have no structural significance. Their use is justified because plagioclase feldspars are the most common and abundant minerals in the Earth’s crust (Fig. 1) and their composition is rather predictable. In the sandine field in Fig. 5, the feldspars ($Or_{50}-Or_{80}$ or $< Or_{50}$) have monoclinic symmetry and K-high albite are triclinic at room temperature (Table 2). Pure albites, both low- and high-temperature forms, have triclinic symmetry. Sodic plagioclase (oligoclase) feldspars are more common in granite, Ca-rich feldspars (labradorite) in mafic rocks (e.g., gabbro) and intermediate plagioclase such as andesine exists more in intermediate igneous rocks (e.g., andesite).

Alkali feldspars have a range of chemical compositions between the two end members, i.e., $KAlSi_3O_8$ and $NaAlSi_3O_8$. The K-feldspar polymorphs, sanidine, orthoclase, microcline, and adularia have identical chemical compositions. Both, orthoclase and sanidine are monoclinic K-feldspars. Sanidine occurs in volcanic and subvolcanic rocks, whereas orthoclase is more common in plutonic rocks. Microcline is a triclinic K-feldspar and has a characteristic cross-hatched tartan pattern of twinning observed under a petrographic microscope (Fig. 6A). Adularia occurs in low-temperature hydrothermal veins. Anorthoclase (K-high albite) is the only alkali feldspar that is not a K-feldspar. It is a Na-rich feldspar that is triclinic and shows very fine cross-hatched twinning.

The high-temperature series of mixed crystals is quite continuous between the end-member orthoclase and albite, and also between albite and anorthite. However, under low-temperature conditions, these phases undergo structural changes and tend to segregate. The segregation results in the formation of lamellar aggregates whose composition is similar to that of the end members. The lamellar aggregates, which are composed of considerable amounts of alkali feldspar and albite, are referred to as ‘perthite.’ Except for authigenic K-feldspar, which is formed through reconstitution and precipitation, most alkali feldspars usually contain

Table 2 Unit-cell dimensions, chemical formulae and specific gravity of end members of feldspars.

Mineral name	Ideal chemical formula	Crystal system and unit cell	Specific gravity (Mg m^{-3})
Orthoclase	KAlSi_3O_8	$a = 0.856 \text{ nm}$, $b = 1.300 \text{ nm}$, $c = 0.719 \text{ nm}$ $\alpha = 90^\circ$, $\beta = 116.01^\circ$, $\gamma = 90^\circ$	2.56
Sanidine	KAlSi_3O_8	$a = 0.860 \text{ nm}$, $b = 1.303 \text{ nm}$, $c = 0.718 \text{ nm}$ $\alpha = 90^\circ$, $\beta = 116^\circ$, $\gamma = 90^\circ$	2.56
Microcline	KAlSi_3O_8	$a = 0.859 \text{ nm}$, $b = 1.297 \text{ nm}$, $c = 0.722 \text{ nm}$ $\alpha = 90.6^\circ$, $\beta = 115.9^\circ$, $\gamma = 87.7^\circ$	2.56
Low albite	$\text{NaAlSi}_3\text{O}_8$	$a = 0.814 \text{ nm}$, $b = 1.279 \text{ nm}$, $c = 0.716 \text{ nm}$ $\alpha = 94.3^\circ$, $\beta = 116.6^\circ$, $\gamma = 87.7^\circ$	2.61
High albite	$\text{NaAlSi}_3\text{O}_8$	$a = 0.816 \text{ nm}$, $b = 1.287 \text{ nm}$, $c = 0.711 \text{ nm}$ $\alpha = 93.5^\circ$, $\beta = 116.4^\circ$, $\gamma = 90.3^\circ$	2.61
Anorthite	$\text{CaAl}_2\text{Si}_2\text{O}_8$	$a = 0.818 \text{ nm}$, $b = 1.288 \text{ nm}$, $c = 1.417 \text{ nm}$ $\alpha = 93.2^\circ$, $\beta = 115.8^\circ$, $\gamma = 91.2^\circ$	2.76

varying amounts of Na in their structure and are thus more or less perthitic. The morphology of soil perthite crystals with a second phase, most likely albite, in a host crystal of K-feldspar is shown in Fig. 6B. The chemical composition of feldspars varies widely. Reasonable amounts of elements other than Na, Ca and K, may be present in feldspars. Other elements that occur in trace to small amounts in feldspars include Ti (titanium), iron (both in Fe^{3+} and Fe^{2+} forms), Mn, Mg, Ba and Sr (strontium).

Feldspars are present in nearly all soils, but their quantities vary with the intensity and capacity factors of weathering reactions. They are absent or in only small quantities in strongly weathered soils, even though the parent material contains considerable quantities of those minerals. Some feldspars may occur in humid tropical soils that contain relatively fresh rock materials due to erosional and depositional processes. Feldspars are common in the silt and sand fractions of young to moderately developed soils representing various soil parent materials and soil-forming conditions. Alkali feldspars are even present in the clay fraction of moderately weathered soils.

Weathering of feldspars

The weathering of feldspars occurs at structural defects, particularly at the boundary of twinned and untwinned domains. Both nonstoichiometric and stoichiometric dissolution behaviors have been reported in controlled studies using different feldspars, and depend on the mineral (such as, defects, exsolution) and solution properties (e.g., pH and ionic strength) (Casey et al., 1989; Muir et al., 1989; Nesbitt et al., 1991; Welch and Ullman, 1993; Stillings and Brantley, 1995). Casey et al. (1989) showed nonstoichiometric dissolution of labradorite in acid solutions (pH 1 to 3), where H^+ ions infiltrated to a depth of several tens of nanometers, selectively removed Na^+ , Ca^{2+} and Al^{3+} and produced an amorphous Si-rich layer at the mineral surface. At higher pH values, however, only limited penetration of H^+ ions was observed, and dissolution occurred at the immediate mineral surface. With secondary ion mass spectrometry (SIMS) and X-ray photoelectron spectroscopy (XPS), Muir et al. (1989) produced similar conclusions from labradorite dissolution in solutions of pH 3.5 and 5.7. Stillings and Brantley (1995) observed stoichiometric dissolution for microcline and bytownite and nonstoichiometric for oligoclase and labradorite at 25 °C and pH 3.0. The preferential release of Ca and Al in oligoclase was attributed to the impurity phases, and apparent nonstoichiometric dissolution in labradorite possibly occurred due to its exsolution texture, that caused the preferential Ca and Al release. Chou and Wollast (1984) studied the dissolution of albite with a continuous flow reactor and observed three steps in the dissolution of fresh feldspar. The first step involves instantaneous and reversible rapid exchange of Na^+ with H^+ , which is followed by the build-up of a residual layer that is depleted in Na and also Al under acidic conditions. Finally, at a steady-state a congruent dissolution stage is formed, where the rate is controlled by a surface reaction between the residual layer and the solution.

The rates of dissolution for the main feldspar minerals in the acidic pH range from the data compiled by Blum and Stillings (1995) are presented in Fig. 7. There is a strong dependence of mineral dissolution on solution pH, which reflects the importance of a proton-promoted dissolution mechanism. There is general agreement that feldspar dissolution occurs by protonation of Al surface sites in the tetrahedral framework. The dissolution behavior of feldspars is consistent with Goldich's relative order of stability of the feldspar minerals to natural weathering: anorthite < bytownite < labradorite < andesine < oligoclase < albite < K-feldspars. The dissolution data show the importance of the chemical characteristics of minerals, with Ca, Al-rich plagioclases dissolving faster than Na, Si-rich plagioclases in similar solutions.

The rates of experimental dissolution of albite and K-feldspar are quite similar (Fig. 7A and B), which contrasts with observations in most soils, including acidic soils, where K-feldspars commonly weather more slowly than sodic plagioclase. This has been explained by the soil porewater chemistry, which tends to be closer to saturation with respect to K-feldspars than albite (Blum and Stillings, 1995).

Organic acids have been shown to have enhanced feldspar dissolution in soils, however, there is still some debate on this subject. Ligands of complexing organic acids may play a significant role in feldspar dissolution, particularly their ability to complex Al from the minerals. At concentrations of organic acids that might exist in natural systems, their effect on feldspar dissolution is generally small. Drever and Stillings (1997) observed that the effect of 1 mM oxalic acid on feldspar dissolution ranged from none to

Fig. 7 Rate of dissolution of feldspars as a function of pH (A) Plagioclase feldspars of different compositions and (B) K-feldspars. The data for both feldspars were compiled from several studies. From Blum AE and Stillings LL (1995) Feldspar dissolution kinetics. In: White AF and Brantley SL (eds.) Chemical Weathering Rates of Silicate Minerals, Reviews in Mineralogy, Vol. vol. 31, pp. 291–346. Washington, DC: Mineralogical Society of America.

enhancement by a factor of 15, and that humic acids do not significantly affect feldspar dissolution. [van Hees et al. \(2002\)](#) studied the effects of naturally occurring organic acids in soils on microcline and labradorite dissolution, and at pH 5 the rate increased from 2.4 to 5.7 times from aqueous dissolution at the same pH, which was considered to be a significant enhancement. Organic acids, such as oxalic and citric acids, at concentrations likely to occur in soils may increase the rates of dissolution of feldspars by less than an order of magnitude, through their ability to complex Al around pH 5 ([Wilson, 2004](#)). At lower pH values increased dissolution effects are more attributable to the higher proton concentration rather than to the complexing nature of the acid. Aluminum-rich feldspars (e.g., Ca-rich plagioclase) are more susceptible to attacks by organic acids than K-feldspars due to preferential adsorption of organic acids at Al sites on mineral surfaces that cause ligand promoted dissolution.

In the natural environment, the steady state dissolution step is the main process controlling the weathering of feldspars. If the residence time of the solution in contact with the rocks is sufficiently long, the dissolved ion concentrations may reach an oversaturation stage that may cause the precipitation of secondary minerals. Kaolinite and halloysite are the most common products of feldspar weathering in soils and saprolite (Robertson and Eggleton, 1991 and Jeong, 1998 in [Wilson, 2004](#)). Weathering reactions of feldspars to kaolinite can be written as:

Gibbsite has also been reported as a weathering product at early stages in soils and saprolites. Few studies have identified smectite formation from feldspar weathering in more closed and alkaline conditions ([Wilson, 2004](#)).

Micas

Micas are 2:1 phyllosilicates with tightly held, non-hydrated, interlayer cations balancing a high layer charge. Primary attention has been given to those micas with K^+ as the interlayer cation because they are the abundant and important micas in most soils. Micas are abundant in many rocks, e.g., shales, slates, phyllites, schists, gneisses, and granites and in sediments derived from these and other rocks. The micas in soils are mainly inherited from soil parent materials. Micas serve as precursors for expandable 2:1 phyllosilicates, i.e., vermiculites and smectites, to which micas are transformed by replacement of the interlayer cations (usually K^+) by hydrated cations. Micas serve as an important source of K for plant growth in soils.

The 2:1 layer of micas comprises an octahedral sheet sandwiched between two tetrahedral sheets as depicted in [Fig. 8](#). Micas can be classified as dioctahedral or trioctahedral, depending on the types and locations of cations in the octahedral sheets ([Table 3](#)). In trioctahedral micas such as biotite, all three octahedral positions are filled with divalent cations (e.g., Mg^{2+} , Fe^{2+}), whereas in dioctahedral micas such as muscovite ([Fig. 8](#)), only two out of three octahedral cations are filled with trivalent cations (e.g., Al^{3+} , Fe^{3+}). Isomorphous substitution in the mica structure creates excess negative charge, which results in a strong coulombic attraction for charge-compensating interlayer cations such as K, which is not readily exchanged in standard cation exchange capacity analysis. The negative layer charge in micas arises from combinations of three mechanisms: (1) substitution of Si^{4+} in tetrahedral positions by R^{3+} (primarily Al or Fe), (2) substitution of R^{3+} in octahedral positions by R^{2+} , and (3) vacancies in octahedral positions. The resultant layer charge may originate entirely within the tetrahedral sheet or may originate entirely within the octahedral sheet in some species or may come partly from both sheets. The layer charge of micas is expressed on a formula unit basis ([Table 3](#)).

Muscovite is the most abundant dioctahedral primary mica. In muscovite, excess negative layer charge results from the substitution of Si^{4+} by Al^{3+} in one out of each of four Si in the tetrahedral sheet positions ([Fig. 8](#)). Biotite is the most common trioctahedral mica. Approximately three-quarters of the cation locations in the tetrahedral sheets of biotite are filled with Si^{4+} and about one-quarter is filled with Al^{3+} . The excess negative charge generated by substitution of Si^{4+} by Al^{3+} results in the negative

Fig. 8 Schematic structure of muscovite, two tetrahedral sheets and an octahedral sheet make up the 2:1 layer. The interlayer region is occupied by K^+ ions, the d_{001} spacing in 1.0 nm.

Table 3 Ideal formulae and layer charge of some dioctahedral and trioctahedral micas.

Mineral	Layer charge (mole per formula unit)	Chemical formula
Dioctahedral micas		
Muscovite	1	$K[Si_3Al](Al_2)O_{10}(OH)_2$
Paragonite	1	$Na[Si_3Al](Al_2)O_{10}(OH)_2$
Margarite	2	$Ca[Si_2Al_2](Al_2)O_{10}(OH)_2$
Illite	0.75	$K[Si_{3.5}Al_{0.5}](Al_{1.75}(MgFe(II)_{0.25}))O_{10}(OH)_2$
Phengite	1	$K[Si_{3.5}Al_{0.5}](Al_{1.5}(MgFe(II)_{0.5}))O_{10}(OH)_2$
Glauconite	0.91	$K_{0.81}Ca_{0.05}[Si_{3.75}Al_{0.25}](Al_{0.36}Fe(III)_{0.98})(Mg_{0.45}Fe(II)_{0.24})O_{10}(OH)_2$
Trioctahedral micas		
Biotite	1	$K[Si_3Al](Mg,Fe(II)_3)O_{10}(OH)_2$
Phlogopite	1	$K[Si_3Al](Mg_3)O_{10}(OH)_2$
Clintonite	2	$Ca[SiAl_3](Mg_2Al)O_{10}(OH)_2$
Lepidolite	1	$K[Si_3Al](Li,Al)_3O_{10}(OH)_2$

charge that is localized in the basal O atoms of the tetrahedral sheets where Al substitution occurs. In soils and sedimentary rocks, mica in the clay fraction is usually identified as illite. Illite has been called 'hydrous mica,' 'clay mica,' and 'sericite.' It is commonly dioctahedral, has poorer crystallinity, lower K content and greater H₂O content than muscovite. Glauconite is a green, ferric iron-rich micaceous mineral that forms mainly in marine, estuarine, and occasionally nonmarine sediments. Glauconite structure has many similarities to that of illite, with comparably little minor substitution of Si by Al in the tetrahedral sheet, but it contains considerably more Fe than illite.

After feldspars and quartz, micas are the third most extensive group of minerals in granitic and felsic rocks in general, but less extensive in most mafic rocks. Muscovite and biotite are the most extensive micas in igneous and metamorphic rocks. Phlogopite occurs as a product of the metamorphism of magnesian or dolomitic limestones and in serpentine rocks. Micas are generally more extensive in fine-grained sediments and sedimentary rocks (e.g., shales) than in coarse-textured sedimentary rocks (e.g., sandstones). Shales and slates are usually rich in the fine-grained, illitic-type micas, which are also important minerals in limestones. Illite in sedimentary rocks is apparently detrital, but some might also have been developed or affected by authigenic or diagenetic processes. The contents and species of micas in more recent, unconsolidated parent materials such as glacial tills, loess, and alluvium vary with their origin. Mica group minerals are easily identified by X-ray diffraction of a basally oriented specimen, with two intense peaks at 1.0 and 0.33 nm that remain unaffected by glycerol or heat treatments.

Micas represent a major source of the macronutrient K in soil and thus play an important role in plant nutrition. If the soil solution is low in K⁺ activity, K near the edges of micaceous minerals may be released into solution by exchange with H⁺, Na⁺, Mg²⁺ or Ca²⁺. When the readily exchangeable K is exhausted, fixed K from the interlayer position can also be released. Estimating the capacity of micaceous minerals to supply K to the soil solution is critical for predictions of plant nutrition and growth.

Micas exhibit a strong preference for large weakly hydrated cations such as Cs⁺ (cesium), which has an important environmental application in determining the fate of some radioactive wastes. Radioactive isotopes of Cs have been added to soils for waste disposal and also by deposition of fallout from both nuclear weapon testing and accidents at nuclear energy facilities. The mobility and bioavailability of radiocesium in mineral soils is limited by nearly instantaneous sorption of ¹³⁷Cs⁺ ions at the frayed edges of mica particles followed by their slower fixation by diffusion into interlayer sites within mica crystals. Therefore, micas play a role in restricting the contamination of ¹³⁷Cs⁺ in the terrestrial food chain and the impact on human health.

Structural Fe contents of micas may be substantial. For example, Fe accounts for approximately 23% by mass of ideal biotite (i.e., has a chemical composition close to the pure form). Structural Fe can participate in electron-transfer reactions in soils. Three examples of mica involvement in environmentally significant electron-transfer reactions are the reduction of NO₃⁻ (nitrate) to NH₄⁺ (ammonium), the reduction of Cr(VI) (chromium VI) to Cr(III), and the reductive degradation of chlorinated hydrocarbons in soils and groundwater.

Weathering of micas

The weathering of micas has been well studied because of their importance as a potential source of K for plants in the soil. It has long been known that there was a sharp contrast in the susceptibility to weathering of biotite compared with muscovite. Biotite is known to weather very easily and in contrast, muscovite is often extremely resistant to weathering and persists even in highly weathered soils (Wilson, 2004). The simple transformation of micas to expansible 2:1 phyllosilicates (e.g., vermiculites and smectites), involves exchange of the interlayer K by hydrated cations (e.g., Ca²⁺, Mg²⁺ and Na⁺), solution and reduction of negative charge in the mineral structure. The transformation can occur by layer weathering (most common) and edge weathering or both (Fanning et al., 1989). Layer weathering is more common in the finest illite particles, while larger particles may release K through edge weathering. The former leads to the formation of a regularly interstratified mica-vermiculite or mica-smectite minerals (see Coleman et al., 1963 and Wilson, 1970 in Wilson, 2004). In edge weathering, interlayer K ions are exchanged from several interlayers along the edges of mica particles producing frayed edges, while some of the interlayers remain closed. During the transformation of micas to expansible 2:1 clay minerals there is also a reduction of layer charge in the mineral structure (Norris,

1973). This reduction can result from the oxidation of structural Fe^{2+} to Fe^{3+} , ejection of octahedral cations and proton incorporation into the structure (see Raman and Jackson, 1966 and Gilkes et al., 1972a,b in Fanning et al., 1989 and Scott and Amonette, 1988 in Wilson, 2004).

Mica weathering in the soil can also result from the uptake of interlayer K by plants and decomposition by organic acids excreted by plant roots, fungi or bacteria. Transformation of micas into vermiculite and interstratified minerals has been observed in controlled and field experiments (Hinsinger and Jaillard, 1993; Singh and Goulding, 1997).

The simple transformation of micas produces vermiculite, smectite and interstratified minerals that contain regular or random layers of these minerals. Other minerals, including kaolinite, halloysite, goethite, gibbsite and Al-hydroxy interlayered vermiculites can also result from the weathering of micas (Wilson, 2004).

Common accessory primary minerals

Olivines, pyroxenes and amphiboles are the accessory minerals of soils and are present in the heavy specific-gravity fractions. Weathering of these minerals is one of the major processes in the geochemical cycles of Mg and Fe. The variety of isomorphous substitution in these minerals and their relative ease of weathering make them excellent source minerals for Ca, Mg, and trace elements in soils.

Olivines

Olivines are nesosilicates, with structures consisting of independent SiO_4 tetrahedra. Olivines forms a complete solid solution series between forsterite (Mg_2SiO_4) and fayalite (Fe_2SiO_4) in nature, and have $(\text{Mg, Fe})_2\text{SiO}_4$ as a general formula. Members of the forsterite–fayalite series comprise the most abundant naturally occurring olivines. The structure of forsterite consists of individual Si tetrahedra linked by Mg (and Fe) atoms that are in octahedral coordination (Fig. 9). The O atoms lie in approximately hexagon closely-packed sheets parallel to the (100) plane. The SiO_4 tetrahedra point alternately in opposite directions along the X- and Y-axis. Half of the available octahedral voids are occupied by Mg or Fe atoms and one-eighth of the available tetrahedral voids by Si atoms. Replacement of Mg^{2+} and Fe^{2+} by Mn^{2+} and Ca^{2+} may occur in minerals of the olivine group, for example – Tephroite (Mn_2SiO_4), Knebelite ($(\text{Fe, Mn})_2\text{SiO}_4$), Monticellite (CaMgSiO_4). The most common composition of olivine found on the surface of the Earth is a forsterite-rich olivine with $\sim 10\%$ Fe^{2+} . The Mg-rich olivines are predominant in basic rocks and the Fe-rich varieties in intermediate and acid igneous rocks. Tephroite occurs mainly in metasomatic rocks and Mn deposits, and knebelite is largely restricted to Fe–Mn ore deposits and to metamorphosed manganese sediments.

Olivine in soils weathers rapidly, therefore and it is rarely found in soils. Delvigne et al. (1979) identified three situations for olivine's existence: (i) in rock fragments and sand fraction in the vicinity of large basic or ultramafic outcrops, fresh or moderately weathered rocks that are actively eroding; (ii) in soils formed from recent volcanic deposits, and (iii) in older soils, where olivine has partly transformed into secondary minerals and the olivine core is protected by a cortex of iddingsite or a reaction rim of pyroxene or garnet.

Weathering of olivine

Olivine releases Mg, Fe and other nutrients and potential toxic elements (e.g. nickel, chromium) on weathering. Iddingsite (a mixture of trioctahedral smectite and Fe oxides) has been reported as an alteration pseudomorph after olivine (Eggleton, 1984

Fig. 9 The structure of forsterite (Mg_2SiO_4) parallel to [100] plane. The Si—O bonds are shown in the isolated tetrahedra, which point alternatively in opposite direction along the X and Y axes. The unit-cell is outlined in the red rectangle.

and Smith et al., 1987 in Wilson, 2004). The extent of weathering of these minerals indicates the intensity of chemical weathering of soils in cool humid regions. Where leaching is only moderate, olivines may alter to serpentine or trioctahedral smectite (usually of the saponite type), nontronite, and various ferric hydrates and gels. In an environment where leaching is intense, the degradation products are mixtures of poorly crystallized smectite, kaolinite, halloysite, and Fe oxides such as goethite, hematite, or the noncrystalline precursors of these minerals (Wilson, 2004). In addition to abiotic chemical weathering, olivine can be weathered by microbial activity and by organic acids.

In the last few years, olivine dissolution has received considerable attention because its enhanced weathering has been considered in carbon dioxide (CO₂) removal technology to mitigate anthropogenic climate change (Oelkers et al., 2018). Enhanced weathering involves the dissolution of silicate minerals and Ca and Mg are released, which can react with dissolved CO₂, (HCO₃⁻ (bicarbonate), CO₃²⁻ (carbonate)) and precipitate as carbonate minerals, such as calcite (CaCO₃), dolomite (MgCO₃), and magnesite (CaMg(CO₃)₂). Olivine (forsterite) dissolution implies the sequestration of 4 mol of CO₂ for each mole of olivine:

With both the absence of covalent Si—O—Si bonds and relative weakness of the ionic divalent metal–oxygen bonds in its structure, olivine is among the fastest dissolving silicate mineral, and is considered one of the key minerals in enhanced mineral weathering technology for CO₂ sequestration (Oelkers et al., 2018). The dissolution behavior of forsterite as a function of pH in aqueous solutions containing only Mg, Si, Fe, and simple inorganic acids or bases is depicted in Fig. 10 (Rimstidt et al., 2012; Oelkers et al., 2018). The rate of forsterite dissolution decreases with increasing pH that is typical for the Mg-silicates, and contrasts with that of Al-silicates, which tend to increase with increasing pH under alkaline conditions (Oelkers et al., 2018). To make olivine a viable option for CO₂ sequestration and to enhance weathering, Oelkers et al. (2018) suggested increasing the mineral surface area and decreasing solution pH. Organic ligands generally have a limited influence on rates of forsterite dissolution in acidic solutions. However, under neutral to alkaline conditions organic ligands could potentially absorb and remove Mg that is abundant at the forsterite surface and accelerate mineral dissolution rates.

Pyroxenes and amphiboles

Pyroxenes and amphiboles are two groups of ferromagnesian minerals that are inosilicates with long chains of linked SiO₄ tetrahedra. Pyroxenes consist of single chains of linked SiO₄ tetrahedra, each of which shares two O atoms with its neighboring tetrahedra (Fig. 11A). The top vertices of the tetrahedra of each chain always face the same direction and subsequent chains in the structure have opposite polarity of these vertices, facing alternatively up and down as shown in Fig. 11A. The tetrahedral chains are separated by layers of octahedral sites.

Fig. 10 Steady-state dissolution rate of forsterite at 25 °C as a function of pH, the curve is based on the statistical analysis of published data from several studies by Rimstidt et al. (2012) and drawn based on Oelkers et al. (2018).

Lithium pyroxenes					
Spodumene	LiAlSi ₂ O ₆	0.947	0.841	0.522	110.05

The general chemical formula (formula unit) for pyroxenes is $M_2M_1T_2O_6$, where M_2 refers to cations in a generally distorted octahedral coordination, M_1 refers to cations in a regular octahedral coordination, and T to tetrahedrally coordinated cations. Common pyroxenes and minerals of end members of various groups are listed in Table 4. Magnesium-Fe pyroxenes are a solid-solution between enstatite (Mg₂Si₂O₆) and ferrosilite (Fe₂Si₂O₆) and are also known as orthopyroxenes due to their orthorhombic crystal structure ($\beta = 90^\circ$). Clinoenstatite and clinoferrosilite, the low-temperature monoclinic ($\beta > 90^\circ$) polymorphs of the orthopyroxenes, exist in nature but are rather uncommon. Calcium pyroxenes represent a solid solution between the monoclinic diopside (CaMgSi₂O₆) and hedenbergite (FeMgSi₂O₆), also known as clinopyroxenes. Magnesium-Fe pyroxenes and some of the Ca pyroxenes (e.g., augite) are the most common rock forming pyroxenes.

The structure of amphiboles consists of indefinite double chains along the [001] plane of tetrahedra that are linked together by O atoms, and the tetrahedra share two and three O atoms alternately (Fig. 11B). Double chains are joined together by strips of octahedral sites (M sites). There are four different types of octahedral sites (M1, M2, M3, and M4) in the mineral structure that vary in size. Three smaller size sites (M1, M2, M3) occur sandwiched between two double chains of tetrahedra, and the larger M sites (M4) occupy a peripheral position with respect to the chains (Fig. 11B). Fig. 11B shows an amphibole structure with a series of sandwiches of tetrahedral chains with octahedral sites in between, and each island consists of 5 octahedral sites with every 8 tetrahedra, four on each side. The large gaps (A sites) that are evident in the structure may be empty or partially filled by large cations, such as Na, and are points of weakness in the mineral structure. The bond between the O atoms and the cations linking the tetrahedral chains is weaker than that between the O and Si. Therefore, cleavage takes place diagonally through the crystal structure and does not rupture the Si—O chains.

The general formula of amphiboles may be written as $A_{0-1}B_2C_5T_8O_{22}(OH,F)_2$, where A, B and C are the atoms at sites A, M4, and M1 + M2 + M3, respectively (site as shown in Fig. 11B), and T cations at tetrahedral sites (Deer et al., 1992). The most common cations at each structural site are A— Na⁺, K⁺; B— Na⁺, Ca²⁺, Mg²⁺, Fe²⁺; C— Mg²⁺, Fe²⁺, Al³⁺, Fe³⁺; T— Si⁴⁺, Al³⁺, and hydroxyls (OH⁻) can be replaced by Cl⁻ and F⁻. The composition of amphiboles varies considerably, but four groups can be distinguished based on the cations occupying the M4 sites (or B in the general formula): calcic amphiboles (B = Ca), sodic amphiboles (B = Na), sodic-calcic amphiboles (B = both Na, and Ca in appreciable contents), and iron-magnesium-manganese amphiboles (B = Fe, Mg, Mn). Amphiboles that exist in soils are presented in Table 5.

Many amphiboles are absent in primary igneous rocks or may occur as secondary minerals. The main primary amphiboles of igneous rocks are the Mg-poor riebeckites and the Si-poor basaltic and common hornblendes. Hornblendes are widely distributed in igneous rocks from syenite and granite to gabbro, and in metamorphic rocks such as gneiss, hornblende schist, and amphibolites.

Pyroxenes and amphiboles are largely confined to the sand and silt fractions of soils. Some may occur in the clay fraction of soils that are developed from glacial rock flour not subjected to intensive weathering. The variety of isomorphous substitution in these minerals and their easy weatherability make them excellent sources of trace elements and Ca and Mg in soils.

Table 5 Chemical compositions of amphiboles classified based on the cation occupancy of the B (or M4) position in the mineral structure^a.

Group	Mineral	Cation sites ^b				Anions	Symmetry
		A ₀₋₁	B ₂	C ₅	T ₈	O ₂₂ (OH) ₂	
Iron-magnesium	Anthophyllite	—	(Mg,Fe) ₂	(Mg,Fe) ₅	Si ₈	O ₂₂ (OH) ₂	Orthorhombic
	Gedrite	—	(Mg,Fe) ₂	(Mg,Fe) ₃ Al ₂	Si ₆ Al ₂	O ₂₂ (OH) ₂	Orthorhombic
	Cummingtonite-Grunerite	—	(Mg,Fe) ₂	(Mg,Fe) ₅	Si ₈	O ₂₂ (OH) ₂	Monoclinic
Calcic	Tremolite-actinolite	—	Ca ₂	(Mg,Fe) ₅	Si ₈	O ₂₂ (OH) ₂	Monoclinic
	Hornblende	Na, K ₀₋₁	Ca ₂	(Mg,Fe ²⁺ , Fe ³⁺ , Al) ₅	(Si, Al) ₈	O ₂₂ (OH) ₂	Monoclinic
	Kaersutite	Na	Ca ₂	(Mg,Fe ²⁺) ₄ Ti	Si ₆ Al ₂	O ₂₂ (OH) ₂	Monoclinic
Sodic-calcic	Richterite	Na	NaCa	(Mg,Fe) ₅	Si ₈	O ₂₂ (OH) ₂	Monoclinic
	Katophorite	Na	NaCa	(Mg,Fe ²⁺) ₄ Fe ³⁺	Si ₇ Al	O ₂₂ (OH) ₂	Monoclinic
Sodic	Glaucophane-riebeckite	—	Na ₂	(Mg,Fe ²⁺) ₃ (AlFe ³⁺) ₂	Si ₈	O ₂₂ (OH) ₂	Monoclinic
	Eckermanite-arfvedsonite	Na	Na ₂	(Mg,Fe ²⁺) ₄ (AlFe ³⁺)	Si ₈	O ₂₂ (OH) ₂	Monoclinic

^aBased on Nasse (2000) and Deer et al. (1992).^bSite A – refers to large space that may be empty or partly occupied by large cations (Na and K), B denotes peripheral octahedral, C represents octahedral site sandwiched between adjacent tetrahedra, and T refers to the tetrahedral sites; the subscript number indicates the number of atoms in these sites.

Weathering of pyroxenes and amphiboles

Brantley and Chen (1995) reviewed the rates of dissolution of pyroxenes and amphiboles from published data; they are shown for selective minerals in the acidic pH range in Fig. 12. The rates of dissolution decrease with increasing solution pH for all minerals, however, there are substantial differences between minerals. The dissolution rates of spodumene and jadeite are much faster than those of other minerals and this may be partly because the data were not normalized to the minerals' final surface area. Nevertheless, the figure shows that dissolution rates of Fe-free amphiboles (e.g., anthophyllite) are slower than comparable pyroxenes (e.g., enstatite and diopside). It has also been noted that the dissolution rate constants of the comparable ortho-, and single-chain and double-chain inosilicates decrease with increasing polymerization of the silica tetrahedral structure (Brantley and Chen, 1995).

Both pyroxenes and amphiboles have been shown to weather to hydrous layer silicates involving a topotactic mechanism, i.e., a high degree of structural inheritance by the secondary phase from the primary mineral (Eggleton, 1975 and Eggleton and Boland, 1982 in Wilson, 2004). However, few studies have found that the weathering occurs via the dissolution and precipitation pathway (Nahon and Colin, 1982, and Singh and Gilkes, 1993 in Wilson, 2004).

Pyroxenes tend to weather to chlorite or smectite or both, through partial dissolution of Mg, Ca, and Fe²⁺. Calcite may develop in the environment where the rate of dissolution of Ca is greater than the rate of total breakdown of the pyroxene. As chemical weathering proceeds, all the Ca and Mg, and part of the Si are lost, resulting in progressive enrichment of the residue in kaolinite, ferric oxides and oxyhydroxides, and anatase. Amphiboles broadly follow a weathering sequence similar to pyroxenes. Velbel

Fig. 12 Dissolution rates for some common pyroxenes and amphiboles at 25 °C in the acidic pH range. From Brantley SL and Chen Y (1995) Chemical weathering rates of pyroxenes and amphiboles. (1989) observed stoichiometric dissolution of amphibole that was followed by the precipitation of goethite, gibbsite and kaolinite within and around the mineral.

Some other minerals that are not as abundant as the accessory minerals discussed above, but are still important in soils, are apatite, $\text{Ca}_{10}(\text{PO}_4)_6(\text{F},\text{OH},\text{Cl})_2$ (and its weathering products), tourmaline (a complex boron silicate mineral with a variable chemical composition), epidote ($\text{Ca}_2(\text{Al}_2\text{Fe}^{3+})\text{O}(\text{OH})(\text{Si}_2\text{O}_7)(\text{SiO}_4)$), rutile (TiO_2), ilmenite (FeTiO_3), magnetite (Fe_3O_4), zircon (ZrSiO_4). They are often present in small concentrations (<1%) and not identified in routine soil characterization. Some of these minerals are important sources of nutrient elements to soil, for example, apatite for Ca and phosphorus (P) and tourmaline for boron (B), and others such as zircon are important in tracing the origin of soil parent materials or determining the extent of soil weathering.

Conclusions and future perspectives

Primary minerals are present in all soils and sediments, and they are abundant in the sand and silt size fractions. The weathering of primary minerals is a key process for the terrestrial ecosystem because it is the principal source of many essential plant nutrients, such as Ca, Mg, K, P, Fe, Mn, B. Primary minerals serve as a template for secondary soil minerals or release elements for the precipitation of secondary minerals in soils. The weathering of primary minerals occurs through combinations of physical, chemical and biological processes. Chemical weathering, however, is most important in the ultimate breakdown of primary minerals.

Primary minerals can dissolve congruently or there can be the preferential removal of certain elements from a mineral structure, depending upon the mineral properties and conditions of weathering. Minerals often dissolve at points of weakness in their structure such as dislocations, defects and crystal edges. In ferro-magnesian minerals, such as biotite, olivine, pyroxenes and amphiboles, the oxidation (and even release) of structural Fe^{2+} is a key process of mineral weathering. The weathering of primary silicate minerals is crucial for the release of plant nutrients to maintain a healthy terrestrial ecosystem. Primary minerals buffer acid input in the soil. Forsterite has been considered a potential mineral for CO_2 sequestration in enhanced weathering technology.

Much of the current information about the properties of primary mineral is based on limited studies in young soils and further research using advanced techniques is required to gather knowledge about their occurrence, properties, dissolution behavior in different soil types and weathering environments. There is also little knowledge about the properties and dissolution behavior of many accessory primary minerals that occur in small quantities, which requires more research.

Abstract

The clay fraction of soils consists of mineral particles $<2\ \mu\text{m}$ in diameter, with the most abundant component being clay minerals based on sheets of tetrahedral and octahedral structural units containing silicon (Si), aluminum (Al), and oxygen (O). These exceedingly small particles crystallize in the aqueous environment at the Earth's surface and are responsible for many of the most important physical and chemical properties of soils such as cation exchange, water holding capacity, ability to supply plant nutrients, shrink–swell properties, and the ability to attenuate pollutants.

Key points

- The clay fraction of soils consists primarily of a variety of phyllosilicate minerals that form as the result of weathering at the Earth's surface.
- The most common and abundant clay minerals are based on 1:1 layer and 2:1 layer structures consisting mainly of Si, Al, and O.
- Structural differences between different clay minerals result in their different chemical and physical properties.
- Differences in the types of soil clay minerals account for much of the chemical and physical variation in soils.

Introduction

The clay fraction of soils consists of mineral particles that are less than 2 μm in equivalent spherical diameter. This is the realm of exceedingly small, crystalline particles dominated by planar arrays of SiO_4 (silicate) structural units and many structural hydroxyls and water. These ‘clay minerals’ crystallize in the aqueous environment at the Earth’s surface from constituent ions released by dissolving (weathering) ‘primary minerals’ such as olivines, pyroxenes, feldspars, micas, quartz, and others that were formed in igneous and metamorphic rocks under extreme heat and pressure within the Earth. Clay minerals are responsible for many of the soil’s most important and characteristic physical and chemical properties. Fundamental soil properties such as cation exchange capacity and shrink–swell properties, and practical considerations such as how well a particular soil will attenuate a specific pollutant, or how much fertilizer phosphorus will be fixed and unavailable to crops, are all influenced by molecular-scale differences in soil clay minerals. Clay minerals are distinguished by their different crystal structures, and there is a close relationship between the crystal structure and the corresponding bulk physical and chemical properties of a particular type of clay mineral.

This chapter draws heavily from [Dixon and Weed \(1989\)](#) and [Dixon and Schulze \(2002\)](#), which contain individual chapters on all the major clay minerals discussed below. Unless otherwise noted, the reader is referred to these texts for additional information. I begin by considering some of the properties of the major chemical elements that make up the clay minerals.

Major element composition of clay minerals

Most of the mass and volume of the Earth’s crust is made up by only a few chemical elements. Oxygen (O) and Si (silicon) alone account for almost 75% of the mass, with most of the remainder, in order of decreasing abundance, consisting of Al (aluminum), Fe (iron), Ca (calcium), Na (sodium), K (potassium), Mg (magnesium), Ti (titanium), H (hydrogen), P (phosphorus), and Mn (manganese) ([Klein and Dutrow, 2008](#)). On a volume basis, oxygen alone accounts for more than 90% of the total volume. Oxygen, as O^{2-} , is the only abundant anion, while the other abundant elements are all cations. Most of these cations have only one stable oxidation state at the Earth’s surface (Al^{3+} , Ca^{2+} , Na^+ , K^+ , Mg^{2+} , Ti^{4+} , H^+ , P^{5+}); Fe (Fe^{2+} , Fe^{3+}) and Mn (Mn^{2+} , Mn^{3+} , Mn^{4+}) are the exceptions. The O^{2-} anions are much larger than most of the positively charged cations. The Earth’s crust, therefore, can be characterized as consisting of large O atoms in an approximately close-packed arrangement held together by attraction to smaller cations located in the interstitial space.

Most of the elements in the crust and in soils occur in minerals, and the elements listed above are major constituents of the most abundant minerals, including clay minerals. Building on the concept of packing O atoms in space, I will consider atoms as rigid spheres, realizing that this is an oversimplified but convenient model for developing the key structural concepts.

Basic structural concepts

Tetrahedra and octahedra

Two distinct structural features occur within the crystal structures of soil clay minerals as a consequence of packing the large O^{2-} ions together in space. The first consists of four O^{2-} ions packed closely together and can be described as three O^{2-} ions arranged in a triangle with the fourth O^{2-} occupying the dimple formed by the other three ([Fig. 1](#)). The centers of the four O^{2-} ions form the apices of a regular tetrahedron, and the small space in the center is called a ‘tetrahedral site.’ Cations located in tetrahedral sites are in fourfold or tetrahedral coordination because they are surrounded by and bonded to four O^{2-} ions.

The second structural feature consists of six closely packed O^{2-} ions. Three of them are arranged in a triangle in one plane, and the other three, also in a triangle but rotated 60° relative to the first three, are in a second plane so that the two triangular groups intermesh ([Fig. 1](#)). The centers of the six O^{2-} ions form the apices of a regular octahedron, and the small space in the center is called an ‘octahedral site.’ Cations located in the octahedral site are said to be in sixfold or octahedral coordination because they are surrounded by and bonded to six O^{2-} ions.

Tetrahedral and octahedral sites differ in an important way. The space that can be occupied by a cation in a tetrahedral site is smaller than the space that can be occupied in an octahedral site. Since cations vary in size, smaller cations tend to occur in tetrahedral sites, somewhat larger cations tend to occur in octahedral sites, and the largest cations must fit into spaces that are larger than octahedral sites. Cations with sizes intermediate between the optimum for the two sites can occur in either site. The Al^{3+} ion, for example, can occur in either octahedral or tetrahedral sites. [Table 1](#) summarizes the structural sites in which cations tend to occur in clay minerals.

Representing crystal structures

Octahedra and tetrahedra are commonly represented using different types of models, each of which portrays the same concept, but highlights different structural features. Sphere-packing models give an impression of the space occupied by the atoms, ball-and-stick

Fig. 1 Spheres closely packed to form a tetrahedron and an octahedron. Note the appearance for the three different ways of drawing the model: as a sphere-packing model (top row), ball-and-stick model (middle row), and a polyhedral model (bottom row). Adapted from Schulze DG (2002) An introduction to soil mineralogy. In: Dixon JB and Schulze DG (eds) *Soil Mineralogy with Environmental Applications*, pp. 1–35. Madison, WI: Soil Science Society of America, with permission.

Table 1 Type of structural sites in which common cations tend to occur in phyllosilicate mineral structures.

Type of site	Cation
Tetrahedral only	Si^{4+}
Tetrahedral or octahedral	Al^{3+} , Fe^{3+}
Octahedral only	Mg^{2+} , Ti^{4+} , Fe^{2+} , Mn^{2+}
Interlayer sites	Na^+ , Ca^{2+} , K^+

models highlight the bonds, while polyhedral models emphasize the tetrahedral and octahedral units (Fig. 1). There is some ambiguity associated with each representation, and it is important to understand the correspondence between, and limitations of, each type of model. Polyhedral models are used here, along with some sphere-packing models.

Tetrahedral and octahedral sheets

The most common and abundant clay minerals belong to a group of minerals called phyllosilicates (from Greek ‘phyllon,’ meaning ‘leaf’) or sheet silicates. A common structural theme in all phyllosilicates is the presence of SiO_4 tetrahedra arranged into sheets. Octahedra arranged into sheets are also present in the structures of phyllosilicates, and in some hydroxide minerals. Different combinations of the two sheets give rise to the different clay mineral structures.

The tetrahedral sheet

The tetrahedral sheet consists of SiO_4 tetrahedra arranged such that three of the four O^{2-} ions of each tetrahedron are shared with three nearest-neighbor tetrahedra (Fig. 2). These shared O^{2-} ions are all in the same plane and are referred to as basal oxygens. Note that adjacent tetrahedra share only one O^{2-} between them (the tetrahedra share apices or corners). The fourth O^{2-} ion of each tetrahedron is not shared with another SiO_4 tetrahedron and is free to be part of other polyhedral elements. These unshared O^{2-} ions are referred to as apical oxygens. Since each basal oxygen contributes a charge of -1 to each Si^{4+} ion, the addition of H^+ ions to the apical oxygens to form hydroxyls should result in an electrically neutral tetrahedral sheet. Such individual tetrahedral sheets do not form stable mineral structures by themselves and only occur in combination with octahedral sheets, as described below.

Fig. 2 shows all the apical oxygens pointing in the same direction, namely, out of the plane of the paper toward the reader in the upper half of the figure. This is the most common arrangement, but structures also occur in which the apical oxygens point alternately in opposite directions.

Fig. 2 The tetrahedral sheet as a sphere-packing model (left half) and a polyhedral model (right half). The upper half of the figure shows the view looking down onto the plane of the sheet, while the bottom half shows the view after rotating the sheet 90° to view the edge of the sheet. Adapted from Schulze DG (2002) An introduction to soil mineralogy. In: Dixon JB and Schulze DG (eds) *Soil Mineralogy with Environmental Applications*, pp. 1–35. Madison, WI: Soil Science Society of America, with permission.

Fig. 3 The octahedral sheet as a sphere-packing model (left half) and a polyhedral model (right half). The top three rows of spheres have been omitted from the sphere-packing model so that the underlying cations, represented here as Al^{3+} , can be seen more easily. The upper half of the figure shows the view looking down onto the plane of the sheet, while the bottom half shows the view after rotating the sheet 90° to view the edge of the sheet. The dioctahedral arrangement is shown here, in which two-thirds of the possible octahedral sites are filled with cations and one-third are empty. Adapted from Schulze DG (2002) An introduction to soil mineralogy. In: Dixon JB and Schulze DG (eds) *Soil Mineralogy with Environmental Applications*, pp. 1–35. Madison, WI: Soil Science Society of America, with permission.

The octahedral sheet

Analogous to the tetrahedral sheet, we can consider the octahedral sheet illustrated in Fig. 3 as an assemblage of octahedra in which adjacent octahedra share two oxygens with one another. In other words, adjacent octahedra share edges. For the arrangement of octahedra shown in Fig. 3, the octahedral sites are occupied by trivalent cations, typically Al^{3+} , and for charge balance, a proton (H^+) must be associated with each O^{2-} . (The H^+ takes up very little space, and the OH^- ion can be considered a sphere of roughly the same size as an O^{2-} ion.) Each OH^- contributes one-half a negative charge to each cation because each OH^- is shared between two octahedra. Each Al^{3+} cation is therefore effectively surrounded by $6 \times 0.5 = 3$ negative charges and the sheet is electrically neutral. Note the pattern of empty and filled octahedral sites. Two of every three possible octahedral sites are filled when trivalent cations are

Fig. 4 Structural scheme of soil minerals based on tetrahedral and octahedral sheets. Adapted from Schulze DG (2002) *An introduction to soil mineralogy*. present in the octahedral sites. This arrangement is called dioctahedral and is the most common in soil clay minerals. If the octahedral sites are filled with divalent cations such as Mg^{2+} , then every possible octahedral site must be occupied to produce an electrically neutral structure. This arrangement is called trioctahedral.

Octahedral sheets, stacked one on top of the other and held together by hydrogen bonds, make up the structure of gibbsite, $\text{Al}(\text{OH})_3$ (Fig. 4), an aluminum hydroxide mineral that occurs in intensively weathered soils. The structure of gibbsite is the simplest in a series of structures containing octahedral sheets.

Phyllosilicate minerals common in soil clays

Phyllosilicates are divided into two groups, 1:1- and 2:1-type minerals, based on the number of tetrahedral and octahedral sheets in the layer structure.

1:1-Type minerals

The 1:1 layer structure

The 1:1 layer structure consists of a unit made up of one octahedral and one tetrahedral sheet, with the apical O^{2-} ions of the tetrahedral sheets being shared with (and part of) the octahedral sheet (Fig. 5A). There are three planes of anions (Fig. 5B). One

Fig. 5 (A) Oblique view of the 1:1 layer structure illustrating the relationship between the tetrahedral and octahedral sheets. Note that adjacent apical oxygens of the tetrahedral sheet (arrows 'a') also define corners of octahedra in the octahedral sheet. Arrows marked 'b' point to OHs that lie directly in the center of the hexagonal rings of tetrahedra, although they appear off-center in this oblique view. (B) Edge view of the 1:1 and 2:1 layer structures, illustrating phyllosilicate nomenclature. Adapted from Schulze DG (2002) An introduction to soil mineralogy. In: Dixon JB and Schulze DG (eds) *Soil Mineralogy with Environmental Applications*, pp. 1–35. Madison, WI: Soil Science Society of America, with permission.

plane consists of the basal O^{2-} ions of the tetrahedral sheet, the second consists of O^{2-} ions common to both the tetrahedral and octahedral sheets (marked 'a' in Fig. 5A) plus OH^- belonging to the octahedral sheet ('b' in Fig. 5A), and the third consists only of OH^- belonging to the octahedral sheet.

Kaolinite

The structure of kaolinite consists of 1:1 layers stacked one above the other. Kaolinite contains Al^{3+} in the octahedral sites and Si^{4+} in the tetrahedral sites (Fig. 4). The 1:1 layer is electrically neutral and adjacent layers are held together by hydrogen bonding between the basal oxygens of the tetrahedral sheet and the hydroxyls of the exterior plane of the adjacent octahedral sheet.

Kaolinite is a common mineral in soils and is the most common member of this subgroup. It tends to be particularly abundant in more weathered soils such as Ultisols and Oxisols (Soil Taxonomy, Soil Survey Staff, 2022) and Acrisols, Ferralsols, and Nitisols (IUSS Working Group WRB, 2022). Kaolinite has very little isomorphous substitution in either the tetrahedral or octahedral sheets and most kaolinite has close to the ideal formula $Al_2Si_2O_5(OH)_4$. The 1:1 layer has little or no permanent charge because of the low amount of substitution. Consequently, cation exchange capacities and surface areas are typically low. Kaolinite in soils typically occurs as thin, rounded, pseudo-hexagonal crystals that can be up to $\sim 2 \mu m$ across (Fig. 6A) and therefore is often concentrated in the coarse clay fraction of a soil.

Kaolinite can form in soils from Al and Si released by the weathering of primary and other secondary minerals. For example, feldspars often weather to kaolinite in soils formed from igneous rocks. Kaolinite can also be inherited from clayey, sedimentary soil parent materials. Soils high in kaolinite are generally less fertile than those in which 2:1 clay minerals dominate. This is because of the low cation exchange capacity of kaolinite, and because the long and/or intense leaching conditions that result in kaolinite becoming the most abundant clay mineral also result in the destruction of most of the weatherable minerals that could provide nutrients to plants.

Halloysite

Halloysite has a 1:1 layer structure similar to that of kaolinite except that the 1:1 layers are separated by a layer of H_2O (water) molecules when fully hydrated (Fig. 4). This water is probably present as hydration shells around a small number of interlayer cations (cations that reside between two adjacent 1:1 or 2:1 layers), although the presence of interlayer cations and the existence of a layer charge to attract them has been difficult to confirm. Halloysite often occurs as tubular (Fig. 6B) or sometimes spherical particles.

Fig. 6 Transmission (TEM) and scanning (SEM) electron micrographs of some soil clay minerals. (A) Pseudo-hexagonal kaolinite crystals (KI) predominate in this TEM image of the 2–0.2 μm fraction of an Oxisol (ST) or Ferralsol (WRB) from Sete Lagoas, Brazil. The rectangular particle labeled TiO_2 is either anatase or rutile, while the darker diffuse clusters are iron oxides, either goethite or hematite. (B) Halloysite tubes from the saprolite below an Ultisol in the Piedmont Region of Alabama, USA. (C) A mixture of 2:1 clay minerals predominate in this TEM image of the $<2 \mu\text{m}$ clay fraction of the Drummer silt loam soil [fine-silty, mixed, superactive, mesic Typic Endoaquolls (ST) or Gleyic Phaeozems (Siltic) (WRB)] from the Purdue Agronomy Center for Research and Education, Tippecanoe County, Indiana. The X-ray diffraction analysis shows the presence of illite, vermiculite, smectite, and hydroxy-interlayered vermiculite together with kaolinite. (D) SEM image of soil smectite quasicrystals. See text for details. (E) TEM image of a $< 100 \text{ nm}$ thin slice of an aggregate from an Iowa Mollisol (ST) or Phaeozem (WRB) showing smectite quasicrystals in situ. See text for details. Halloysite is usually found in soils formed from volcanic deposits, particularly volcanic ash and glass, and it is a common clay mineral in Andisols (ST) or Andosols (WRB). Halloysite forms early in the process of weathering of primary minerals, but it is less stable than kaolinite and transitions to kaolinite with time.

2:1-Type minerals

In contrast to the 1:1 phyllosilicate minerals, which are represented in soils by only two major minerals, the 2:1 minerals are structurally more diverse and are represented by several common mineral species.

The 2:1 layer structure

The 2:1 layer structure consists of two tetrahedral sheets, with one bound to each side of an octahedral sheet (Fig. 5B). There are four planes of anions. The outer two consist of the basal oxygens of the two tetrahedral sheets, while the two inner planes consist of oxygens common to the octahedral sheet and the two tetrahedral sheets, plus the hydroxyls belonging only to the octahedral sheet.

Pyrophyllite

The simple structure of pyrophyllite is a good starting point for discussing 2:1 structures. Pyrophyllite consists of 2:1 layers stacked one above the other (Fig. 4). The tetrahedral sheets contain only Si^{4+} and the octahedral sheet contains only Al^{3+} , resulting in the ideal formula $\text{Al}_2(\text{Si}_4)\text{O}_{10}(\text{OH})_2$. The charge is balanced completely within the 2:1 layer, making the layer electrically neutral, and adjacent 2:1 layers are held together only by weak van der Waals forces. Pyrophyllite occurs only rarely in soils, usually only when it is inherited from low-grade metamorphic rocks.

Micas

Mica minerals have the 2:1 layer structure described for pyrophyllite but with two important differences. First, instead of having only Si^{4+} in the tetrahedral sites, one-quarter of the tetrahedral sites are occupied by Al^{3+} . Because of this substitution, there is an

excess of one negative charge per formula unit in the 2:1 layer. Second, this excess negative charge is balanced by monovalent cations, commonly K^+ , that occupy interlayer sites between two 2:1 layers (Fig. 4). This gives an ideal formula of $KAl_2(AlSi_3)O_{10}(OH)_2$ for a mica mineral with Al in the octahedral sites.

The octahedral sheet can contain either Al^{3+} (the dioctahedral case; Fig. 3) or Mg^{2+} (the trioctahedral case). There are several different mica species because micas can be either dioctahedral or trioctahedral, Fe^{2+} and Fe^{3+} can substitute for Mg^{2+} and Al^{3+} in the octahedral sheet, and Na^+ and Ca^{2+} can substitute for K^+ in the interlayer.

Muscovite, biotite, and phlogopite are the three most common mica group minerals in rocks, and consequently in soils. All three contain K in the interlayer, but they differ in the composition of the octahedral sheet and whether they are di- or trioctahedral. Mica in the clay fraction of soils and sediments differs somewhat from the macroscopic muscovite mica it closely resembles. This clay-size dioctahedral mica is often referred to as illite. Glauconite is another mica mineral that is similar to illite, but it contains more Fe and less Al in its octahedral sheet than illite.

Micas in soils are usually inherited from the parent rock and occur widely in soils derived from various igneous and metamorphic rocks, in soils derived from illitic sedimentary rocks, and from sediments derived from them. In glaciated regions, mica in soils may be a mixture of micas from igneous and metamorphic rocks together with mica or illite from sedimentary rocks. As a result of soil processes, micas can be transformed (weathered) to other minerals, particularly to vermiculites and smectites, and the K^+ released during weathering is an important source of K for plants. The dioctahedral micas such as muscovite are usually more resistant to weathering than trioctahedral micas because the interlayer K^+ ions are held more tightly in the interlayer sites of dioctahedral micas than in trioctahedral micas. Thus, muscovite tends to be the most common mica mineral in soils. The thin, irregularly shape plates in Fig. 6C are a mixture of mica together with vermiculite, smectite, and hydroxy-interlayered vermiculite.

Vermiculites

Vermiculite has a 2:1 layer structure as described for mica, but instead of having a layer charge of ~ 1 per formula unit and K^+ in interlayer positions, vermiculite has a layer charge of 0.9–0.6 per formula unit and contains hydrated exchangeable cations, primarily Ca and Mg, in the interlayer (Fig. 4). A typical formula for an idealized vermiculite weathered from muscovite is $M_{0.75}^+Al_2(Si_{3.25}Al_{0.75})O_{10}(OH)_2$, where M^+ represents charges from exchangeable cations. The lower charge per formula unit of vermiculite, compared to micas, allows the interlayer to open, allowing exchangeable cations to move in and out. The layer charge of 0.9–0.6 per formula unit gives vermiculite a high cation exchange capacity, but a strong affinity for weakly hydrated cations such as K^+ , NH_4^+ (ammonium), and Cs^+ (cesium). Fixation of K^+ in the interlayer positions of vermiculite can be significant in soils that have a large vermiculite content and have not received large amounts of inorganic fertilizers.

Vermiculites in soils are believed to form almost exclusively from the weathering of micas and chlorites. The weathering of micas to vermiculite (or smectite) is believed to occur by replacement of K^+ in the interlayer sites with hydrated exchangeable cations. The integrity of the 2:1 layer is preserved, but there is a reduction in the layer charge. Vermiculite does not swell as extensively as smectite, and this is shown in Fig. 4 by the presence of only two planes of water molecules surrounding the hydrated cations in the interlayer space.

Smectites

The smectite group consists of minerals with the 2:1 structure already discussed for mica and vermiculite, but with a still lower charge per formula weight, namely 0.6–0.2. As for vermiculite, the interlayer contains exchangeable cations (Fig. 4). An idealized formula for a common soil smectite, the mineral beidellite, is $M_{0.33}^+Al_2(Si_{3.67}Al_{0.33})O_{10}(OH)_2$, where M^+ represents charges from hydrated, exchangeable cations, typically Ca^{2+} and Mg^{2+} .

The most common smectite minerals range in composition between three end-members: montmorillonite, beidellite, and nontronite. All are dioctahedral, but they differ in the composition of the tetrahedral and octahedral sheets. Since the layer charge of smectite is low compared to vermiculite, smectites do not fix K^+ as readily as does vermiculite, but since the interlayer cations are not as strongly attracted by the 2:1 layers, they attract more water molecules and as a result, smectite swells more extensively upon wetting than does vermiculite.

The morphology of soil smectite crystals is not well documented. The typical procedures used to separate and concentrate soil clay fractions for examination by electron microscopy rely on dispersion of the clay particles, usually by saturation of the cation exchange sites with Na^+ and rigorous mechanical agitation via sonication, followed by centrifugation to obtain the clay fraction, and then flocculation of the separated clay for further study. Minerals like kaolinite, halloysite, and mica are usually not greatly altered by these procedures and occur as distinct, well-defined crystals (Fig. 6A–C). Smectite, however, can be greatly altered, even to the point of delamination of the individual 2:1 smectite layers during dispersion, and then reforming them upon flocculation in a form that may not have been present in the original sample.

Work by Laird and Thompson (Laird et al., 1991; Laird and Thompson, 2009) sheds light on the morphology of smectite in soils. They studied specimens from the surface horizon of the Webster silty clay loam soil [fine-loamy, mixed, superactive, mesic Typic Endoaquoll (ST); Gleyic Phaeozems (Loamic) (WRB)] on the Wisconsin Age till plain of southern Minnesota and north-central Iowa, USA. The $<0.02 \mu m$ fine clay fraction of this soil is overwhelmingly dominated by smectite and randomly interstratified smectite/illite. Fig. 6D shows ‘reformed smectite quasicrystals’ from the $<0.02 \mu m$ e.s.d (equivalent spherical diameter) fine clay fraction that had been saturated with Na^+ ions, dispersed, centrifuged to obtain the $<0.02 \mu m$ fraction, and then flocculated with $CaCl_2$. A drop of suspension was dried and imaged by scanning electron microscopy. These particles are described as ‘reformed’ smectite quasicrystals because they are believed to have been formed upon flocculation of the delaminated Na^+ -saturated clay

(D.A. Laird, personal communication, Sept. 2022). Most of the flocculated particles are 20–50 μm across, which is considerably larger than the $<0.02 \mu\text{m}$ e.s.d. based on the fractionation conditions. This is attributed to the slow settling velocity of the platy, low density, hydrated, dispersed smectite particles which settle considerably slower in a centrifugal field than more equidimensional particles like quartz and kaolinite with particle densities of $\sim 2.65 \text{ g cm}^{-3}$ (Laird and Thompson, 2009). The delaminated Na^+ -saturated 2:1 layers may be as thin as $\sim 1 \text{ nm}$, but several micrometers in diameter. When the Na^+ ions are replaced with Ca^{2+} ions, the planar surfaces of the 2:1 layers are attracted to the Ca^{2+} ions and water molecules in between. The structure that results is called a *quasicrystal*; there is order between adjacent 2:1 layers, but the structure overall does not have large-scale periodicity like a true crystal. The large, floppy quasicrystals crumple and bend into the randomly shaped particles shown in Fig. 6D.

Fig. 6E shows that similar quasicrystals of smectite occur in soils. For this image, a small ($\sim 2 \text{ mm}$ diameter) field moist, minimally disturbed soil aggregate from the surface horizon of the Webster soil was examined using techniques usually used for biological samples. In brief, the sample was dewatered by solvent exchange, stained, imbedded in epoxy resin, and sectioned with a diamond knife to produce slices $<100 \text{ nm}$ thick. These were then examined by scanning transmission electron microscopy (Laird and Thompson, 2009). Although the focus of the study was on imaging clay–humic complexes, the clay fraction dominated images such as Fig. 6E. Note that the entire field of view is only $\sim 3 \mu\text{m}$ across. The areas labeled QC are interpreted as places where the crumpled and bent quasicrystals of smectite have been sliced perpendicular to the plane of the 2:1 layers, while the more diffuse gray areas are areas where the quasicrystals have been sliced parallel or oblique to the plane of the 2:1 layers. Some of the gray areas may also be organic matter.

Smectites are important minerals in many temperate-region soils. Plant nutrient cations (Ca, Mg, K, and others) are held in a bioavailable form on the cation exchange sites of soil smectites. Soils rich in smectite tend to be very effective at attenuating many organic and inorganic pollutants because of the large surface area and adsorptive properties of the smectites. Smectite quasicrystals shrink upon drying and swell upon wetting. This shrink–swell behavior is most pronounced in Vertisols (ST, WRB) and in vertic subgroups of other soil orders (ST) or Reference Soil Groups with Vertic qualifiers (WRB). The shrink–swell properties lead to cracking and shifting problems when houses, roads, and other structures are built on smectitic soils.

Chlorites

Like mica, chlorite minerals have a 2:1 layer structure with an excess of negative charge. In contrast to mica, however, the excess charge is balanced by a positively charged interlayer hydroxide sheet (Fig. 4), rather than K^+ . The interlayer hydroxide sheet is an octahedral sheet as shown in Fig. 3 and can be either di- or trioctahedral. Instead of being electrically neutral as in gibbsite, the hydroxide sheet has a positive charge caused by substitution of higher-valence cations for lower-valence ones, for example, $\text{Mg}_2\text{Al}(\text{OH})^+_6$. Either octahedral sheet – the one that is part of the 2:1 layer or the interlayer hydroxide sheet – can be dioctahedral or trioctahedral, and can contain Mg^{2+} , Fe^{2+} , Mn^{2+} , Ni^{2+} (nickel), Al^{3+} , Fe^{3+} , and Cr^{3+} (chromium), resulting in many different mineral species.

Chlorite minerals in soils are often primary minerals inherited from either metamorphic or igneous rocks. They may also be inherited from sedimentary rocks such as shales, or from hydrothermally altered sediments. Chlorites are rather infrequent minerals in soils, and when present they generally occur in small amounts. Chlorite weathers to form vermiculite and smectite, and the ease with which chlorites break down makes them sensitive indicators of weathering.

Hydroxy-interlayered vermiculite and smectite

Hydroxy-interlayered vermiculite and smectite can be considered a solid solution with vermiculite or smectite as one end-member and chlorite as the other. Hydroxy-interlayered minerals form as Al^{3+} released during weathering hydrolyzes and polymerizes to form large polycations with a postulated formula of $\text{Al}_6(\text{OH})_{15}^{3+}$ (or similar) in the interlayers of vermiculite and smectite. These polycations balance some of the charge of the 2:1 layer. The combination of a 2:1 layer with hydroxy Al in the interlayer gives a structure similar to that of chlorite (Fig. 4). Thus, these minerals have also been called secondary chlorites. The degree of filling of the interlayer with hydroxy Al can vary from none to almost complete, with properties of the clay varying accordingly. The interlayer hydroxy Al is not exchangeable with other cations and its presence reduces the cation exchange capacity of smectite or vermiculite almost linearly as a function of the amount of Al adsorbed in the interlayer.

Interlayer hydroxy Al prevents smectite from shrinking and swelling as it normally would because the interlayer surfaces are blocked, and the movement of exchanging cations and water molecules is restricted. In vermiculite, interlayer hydroxy Al reduces K^+ fixation by lowering the exchange capacity and by preventing the interlayer from collapsing around the K^+ . The positively charged hydroxy interlayers also provide potential sites for anion adsorption. Hydroxy-interlayered vermiculite and smectite are most common in Alfisols and Ultisols (ST) and Luvisols, Acrisols, Retisols, Lixisols, and Alisols (WRB). Within a given soil profile, they tend to be most abundant near the soil surface where weathering is most intense.

Interstratification in phyllosilicates

Because of the structural similarities of all the phyllosilicate minerals just discussed, phyllosilicates in soils do not always occur as discrete particles of mica, vermiculite, smectite, chlorite, or kaolinite. For example, instead of being made up of a stack of identical 2:1 vermiculite layers, one physically discrete particle may consist of a mixture of both mica and vermiculite layers instead. Such minerals are referred to as ‘mixed-layer’ or ‘interstratified minerals.’

Different types of interstratified minerals have been identified. Two-component systems include: mica–vermiculite, mica–smectite, mica–chlorite, kaolinite–smectite, and others. Three-component mixed layer systems can also occur. The sequence

of layers can be either regular or random. A regularly interstratified mineral consisting of two types of layers denoted by A and B could have a sequence such as ABABAB ..., or ABBABBABB ..., or any other repeating sequence. In a randomly interstratified mineral, the sequence of layers is random – for example, ABBABAABBAAA Random interstratification of layer-silicates is more common in soils than regular interstratification, but regular interstratification, especially in weathering micas, is not rare.

Partial removal of interlayer K from micas or of interlayer hydroxide from chlorite is one way that interstratified minerals can form in soils. Other possibilities include fixation of adsorbed K^+ by some vermiculite layers to give mica-like layers, and the formation of hydroxide interlayers to produce chlorite-like layers. There is also the possibility that random interstratification may be an artifact of the laboratory methods used to disperse and isolate the soil clay fraction for identification and characterization.

Palygorskite and sepiolite

Palygorskite and sepiolite are considered phyllosilicates but are distinct structurally from the typical 1:1 and 2:1 layer structures. Both minerals have continuous tetrahedral sheets, but adjacent bands of tetrahedra within one tetrahedral sheet point in opposite directions rather than in one direction as in the 1:1 and 2:1 structures. The result is a structure that can be described as ribbons of 2:1 layers joined at their edges, as illustrated in Fig. 7. Water molecules occur in the spaces between the ribbons. The 2:1 ribbons are wider in sepiolite than in palygorskite. Both minerals have a fibrous morphology in contrast to the platy morphology of most 1:1 and 2:1 minerals.

Palygorskite and sepiolite are often found in soils of arid and semiarid environments, either inherited from the soil parent material or as products of pedogenesis. The stability of both minerals requires alkaline conditions and strong Si and Al activity in solution, conditions that are most likely to occur in arid and semiarid soil environments.

Fig. 7 Structural models of representatives of three other aluminosilicate mineral groups that occur frequently in soils. All three are drawn to the same scale. Adapted from Schulze DG (2002) An introduction to soil mineralogy. In: Dixon JB and Schulze DG (eds) *Soil Mineralogy with Environmental Applications*, pp. 1–35. Madison, WI: Soil Science Society of America, with permission.

Other minerals that occur in the clay fraction of soil

The phyllosilicate clay minerals described above are the most abundant and common in most soils, and they are the minerals that are usually considered to make up the 'clay minerals' group. Phyllosilicates, however, are not the only minerals that occur in the soil clay fraction, nor are they the only minerals that form as primary minerals from igneous and metamorphic rocks weather in soils. Several additional minerals or mineral groups require mention also. Some occur only in particular soils, others occur in many different types of soils, but usually only at low concentrations.

Zeolites

Zeolites are a large group of aluminosilicate minerals that consist structurally of SiO_4 tetrahedra arranged in ways that result in large amounts of pore space within the crystals (Fig. 7). Aluminum substitutes for Si in the tetrahedral sites and, as a result, the (Si,Al) O_4 framework has a net negative charge. The charge is balanced by cations that reside in the channels and pores together with water molecules. Because the cations are exchangeable, zeolites have cation exchange properties similar to the phyllosilicates, but, because the tetrahedral framework of the zeolites is rigid and the size of the pores is fixed, small cations can move into and out of the pores freely, while larger cations are excluded. Thus, zeolites are often referred to as 'molecular sieves' because of their very selective cation exchange properties. Zeolites are relatively rare in soils because they weather and dissolve easily in humid regions, but they occur in some soils of arid regions.

Allophane and imogolite

The aluminosilicate minerals discussed above have three-dimensional crystal structures, with atoms packed together in a more or less regular manner over relatively long distances (e.g., 10s of nanometers). They exhibit long-range order. Two other aluminosilicates, allophane and imogolite, exhibit short-range (or local) order. Structures with short-range order exhibit order over several nanometers, but on a larger scale the structure is disordered.

Allophane consists chemically of variable amounts of O^{2-} , OH^- , Al^{3+} , and Si^{4+} , and is characterized by short-range order and a predominance of Si—O—Al bonds. It consists of small (3.5–5.0 nm) spheres. The spheres clump together to form irregular aggregates. Imogolite consists of tubes several micrometers long with an outer diameter of 2.3–2.7 nm and an inner diameter of approx. 1.0 nm. The tubes consist of a single dioctahedral sheet with the inner surface OH replaced by SiO_3OH groups (Fig. 7). Several individual tubes are arranged in bundles 10–30 nm across to give thread-like particles several micrometers long (Fig. 6F).

Allophane and imogolite usually occur as weathering products of volcanic ash and are important minerals in Andisols (ST) and Andosols (WRB). Imogolite has also been identified in the Bs horizons of Spodosols (ST) and Podzols (WRB). Allophane and imogolite can adsorb many specific inorganic and organic compounds. Andisols (ST) and Andosols (WRB), for example, usually fix large amounts of phosphate, making it unavailable to plants, and the large amounts of organic matter common in Andisols (ST) and Andosols (WRB) may be due, in part, to adsorption of organic molecules by allophane and imogolite. Soils containing large amounts of allophane and imogolite usually have unique physical properties such as a low bulk density, high water-holding capacity, high liquid and plasticity limits, and a thixotropic consistence.

Aluminum hydroxide minerals

Gibbsite, which has already been mentioned as simply a stack of octahedral sheets containing Al^{3+} in the octahedral sites (Fig. 4), occurs in situations where weathering and leaching have been intense or long. Gibbsite often occurs in Ultisols and Oxisols (ST) and Acrisols, Ferralsols, and Nitisols (WRB), and can be important in the fixation of phosphate fertilizers.

Iron oxide minerals

Iron is almost as abundant as Al in the Earth's crust, and one or more strongly colored iron oxide minerals are ubiquitous accessory minerals in almost all soil clays. Goethite (FeOOH) is the most common soil iron oxide mineral and accounts for the yellowish-brown colors of many soils. Hematite (Fe_2O_3) is common also and accounts for the red colors of many soils. Lepidocrocite (FeOOH) (orange) occurs in noncalcareous hydromorphic soils, while maghemite (Fe_2O_3) (reddish brown) occurs in some soils of the tropics and subtropics. Two poorly crystalline minerals, ferrihydrite ($\sim\text{Fe}_5\text{HO}_8 \cdot 4\text{H}_2\text{O}$) (reddish brown) and schwertmannite [$\text{Fe}_8\text{O}_8(\text{OH})_6\text{SO}_4$] (yellowish brown), occur in surface environments when waters rich in Fe^{2+} are exposed and rapidly oxidized in the presence of organic compounds (ferrihydrite) or sulfate (schwertmannite). Lithogenic magnetite (Fe_3O_4) (black) is often found in the sand fraction of soils.

The surfaces of iron oxide minerals are highly reactive and can sorb and fix phosphate, many transition metals, and organic compounds. Oxidation–reduction reactions are an important aspect of soil iron oxide mineralogy. Iron oxide minerals can be dissolved under reducing conditions and then be reprecipitated, often in a different mineral form, when oxidizing conditions return. The spatial distribution of iron oxide minerals that develop under redoximorphic conditions are important indicators of the patterns of water saturation and redox conditions that occur in soils over time.

Manganese oxide minerals

Manganese is about 50 times less abundant in the Earth's crust than Fe, so minerals containing large amounts of Mn are considerably less abundant. Nevertheless, some Mn oxide minerals occur in almost all soils. Mn oxides in soils are often formed in response to microbially mediated oxidation of Mn. These crystals have structures and chemical formulas similar to those of birnessite $((\text{Na,Ca})(\text{Mn}^{3+}, \text{Mn}^{4+})_7\text{O}_{14} \cdot 2.8\text{H}_2\text{O})$. The Mn^{4+} and Mn^{3+} in manganese oxide minerals is reduced to soluble Mn^{2+} under relatively mild reducing conditions, making Mn oxide minerals important in many soil oxidation–reduction reactions, including enzyme reactions associated with soil carbon cycling. Like Fe oxides, Mn oxides have a large capacity to adsorb both trace metals and phosphate ions in soils.

Titanium oxide minerals

Titanium is slightly more abundant than Mn in the Earth's crust, and two Ti minerals, anatase and rutile (both TiO_2), occur widely in soil clays. The Ti-oxide minerals, however, are relatively inert chemically and have a negligible impact on most soil properties. Fig. 6A shows a rectangular Ti-oxide mineral in association with kaolinite in the clay fraction from an Oxisol (ST) or Ferralsol (WRB).

Carbonates, sulfates, and soluble salts

In soils of semiarid to arid climates, calcite (CaCO_3), gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$), and an array of evaporite minerals (minerals with solubilities greater than or equal to gypsum) often occur co-associated with the aluminosilicate and oxide minerals discussed above. The chemical and physical impacts of these minerals on soil processes varies greatly, depending on the amount and type of mineral present.

Summary

The clay fraction of soils consists of a variety of fine-grained secondary minerals that are formed as primary minerals in igneous and metamorphic rocks weather in the aqueous environment at the Earth's surface. The most common soil clay minerals are a variety of aluminosilicate minerals with chemical structures based on planar sheets of Si tetrahedra and Al octahedra. These aluminosilicate clay minerals are co-associated with a variety of Fe, Mn, and Ti oxide and hydroxide minerals, as well as carbonate, sulfate, sulfide, and chloride minerals, depending on the particular soil environment. Minerals in the soil clay fraction impart many of the physical and chemical properties that we associate with soils including cation exchange capacity, water holding capacity, shrink-swell capacity, and other properties.

Abstract

Short-range ordered aluminosilicates, represented by allophane and imogolite, occur in large quantities in Andosols and to a lesser degree in Podzols. With their nano-scale crystallinity, these minerals contribute to a large specific surface area and reactive functional groups and, therefore, strongly influence the physicochemical properties of soils, such as large sorption capacity of phosphate and organic matter, high water retention, and low bulk density. In this chapter, the formation and distribution, identification, and fundamental chemical and physical properties of these minerals are described, together with their agricultural and environmental importance.

Key points

- The formation and distribution of short-range ordered (SRO) aluminosilicates (allophane and imogolite) are explained.
- Identification and structural properties of SRO aluminosilicates, and their reaction with anions, cations, and organic matter are described.
- The environmental and agricultural importance of SRO aluminosilicates is discussed, including nutrient availability, 'heavy' metal sorption, organic matter preservation, and agricultural productivity.

Introduction

Short-range ordered (SRO) aluminosilicates in soils consist primarily of allophane and imogolite, which have nano-sized spherical (allophane, Fig. 1) and tubular (imogolite, Fig. 2) structures, respectively. They also include imogolite precursors (proto-imogolite). These SRO aluminosilicates have been variously described as amorphous, non-crystalline, poorly crystalline, nano-crystalline, and SRO materials, minerals and aluminosilicates. However, 'amorphous' and 'non-crystalline' are not technically correct terms for allophane and imogolite as they possess SRO structures; allophane was previously assumed to be amorphous (non-crystalline) because it does not show clear X-ray diffraction patterns. 'Nano-crystalline' is not widely used but may be a more suitable descriptor than SRO because imogolite has long-range order in the longitudinal direction.

Large amounts of SRO aluminosilicates are predominantly found in soils derived from volcanic ash parent materials, but they also occur in other soils under a variety of parent materials (Parfitt, 2009). Their abundance is commonly estimated by selective dissolution using acid oxalate, as acid oxalate-extractable Si (Si_o) and Al (Al_o) are derived from SRO aluminosilicates and organo-Al complexes (see 'Identification' section below). Organo-Al complexes are estimated by sodium pyrophosphate extraction (Al_p), and hence the $\text{Al}_o - \text{Al}_p$ fraction is attributed to SRO aluminosilicates. The Al/Si (aluminum/silicon) ratio, calculated by $(\text{Al}_o - \text{Al}_p)/\text{Si}_o$, is 2 for imogolite and ranges from 1 to 2 for allophane. Allophane with an Al/Si ratio of 2 is called Al-rich or proto-imogolite allophane, whereas that with an Al/Si ratio of 1 is termed Si-rich allophane.

The SRO aluminosilicates are characterized not only by their poor crystallinity, but also by their small particle size which imparts a large specific surface area, and their variable surface charge properties. These characteristics make them important ion exchange

materials even when present at relatively low concentrations. The SRO aluminosilicates also play important roles in regulating Al^{3+} and H_4SiO_4 (orthosilicic acid) activities of the soil solution, chemical and physical stabilization of organic matter (OM) and soil physical properties, such as bulk density and water retention. Consequently, SRO aluminosilicates take part in a number of environmental- and agricultural-related processes, including solute transport, 'heavy' metal behavior, soil OM accumulation, and agricultural productivity.

Formation and distribution

Short-range ordered aluminosilicates (allophane and imogolite) form as metastable phases in solutions with high H_4SiO_4 activity (X-axis of Fig. 3) and/or high Al^{3+} activity relative to pH (3 pH + log Al^{3+} Y-axis of Fig. 3). High H_4SiO_4 and Al^{3+} activities are frequently achieved in soils derived from volcanic ejecta, which dissolves at a high rate due to its small particle size, glassy nature,

Fig. 3 Stability diagram for selected Al hydrous oxide and aluminosilicate solid phases. Syn, synthetic.

and high porosity (Ugolini and Dahlgren, 2002). Nevertheless, SRO aluminosilicates can be found in soils from other parent materials if composition of the solution allows for their formation. The favorable pH range for allophane and imogolite formation is mildly acidic to neutral conditions ($\text{pH} = 5\text{--}7$; Dahlgren et al., 2004). At more acidic pH values, these minerals tend to dissolve or not form. Under supersaturated conditions, nucleation of allophane and imogolite is kinetically favored over more crystalline minerals (e.g., kaolinite) because of the lower solid–solution interfacial tension of more soluble phases (i.e., SRO aluminosilicates) (Stumm, 1992). Based on nuclear magnetic resonance (NMR) analysis, the process of formation of allophane from volcanic glass under soil conditions is proposed as the reaction of a gibbsite-like sheet that is formed from Al initially released from volcanic glass and H_4SiO_4 that is subsequently released from a silica gel-like polymer in volcanic glass (Hiradate and Wada, 2005). Because of the high solubilities of allophane and imogolite, they dissolve, releasing Si and Al, which then re-precipitate as less soluble, but more thermodynamically stable crystalline minerals (e.g., kaolinite, halloysite, and gibbsite) with time; the Ostwald ripening process.

Short-range ordered aluminosilicates have a disproportionate influence on soil properties, as explained later in this chapter. Their content is a key criterion for Andosols (IUSS Working group WRB, 2022), corresponding to Andisols in USDA Soil Taxonomy (Soil Survey Staff, 2022) and Podzols (WRB, Spodosols in USDA Soil Taxonomy), as well as organo-Al/Fe complexes and ferrihydrite. The $\text{Al}_0 + 1/2\text{Fe}_0$ quantity, where Al_0 originates from dissolution of SRO aluminosilicates and organo-Al complexes and Fe_0 from ferrihydrite and organo-Fe complexes, should be 20 g kg^{-1} (or 4 g kg^{-1} for young volcanic soils) or more for andic soil properties and 5 g kg^{-1} or more for a spodic horizon.

Soils derived from volcanic ejecta frequently have large contents of SRO aluminosilicates, which allows them to be classified as Andosols. The materials comprising volcanic ejecta, such as volcanic glass, quickly dissolve leading to supersaturated soil solutions and the formation of allophane and imogolite. Because of the limited translocation of Al^{3+} at pH values >5 and the low dispersibility of allophane and imogolite, they are generally believed to form in situ and show minimal translocation within the soil profile of Andosols (Dahlgren et al., 2004).

Depending on H_4SiO_4 activity in the soil solution, Al-rich allophane (elemental ratio of Al:Si $\approx 2:1$), Si-rich allophane (Al:Si $\approx 1:1$) and halloysite are commonly formed from volcanic ejecta. Under low H_4SiO_4 activity ($< \sim 10^{-3.45}$; Churchman and Lowe, 2012), Al-rich allophane, which is the most common type, forms, whereas greater H_4SiO_4 activity ($> \sim 10^{-3.45} \text{ mol L}^{-1}$) favors the formation of Si-rich allophane and/or halloysite (Churchman and Lowe, 2012). The rate of tephra deposition, climate and soil depth, among others, influence H_4SiO_4 activity, which is high in drier sites with limited leaching and in deeper soil layers, and low in humid regions and well-drained sites (Churchman and Lowe, 2012).

Andosols can be divided into silandic and aluandic subgroups based on the abundance of SRO aluminosilicates. Silandic Andosols ($\text{Si}_0 \geq 6 \text{ g kg}^{-1}$) are dominated by SRO aluminosilicates, whereas aluandic Andosols ($\text{Si}_0 < 6 \text{ g kg}^{-1}$) have a predominance of organo-Al complexes. Aluandic Andosols are also called non-allophanic Andosols. Soil pH is considered a key factor leading to the formation of SRO aluminosilicates with the polymerization of Al^{3+} at mildly acid to neutral pH values. Allophane and imogolite formation is favored under low OM content and higher pH conditions (5–7) which may result from the rapid dissolution of colored volcanic glass (a base-rich glass) and/or lower precipitation and leaching. On the contrary, allophane and imogolite may dissolve under low pH conditions (< 5 ; Dahlgren et al., 2004) because of high precipitation and/or the low base element content of non-colored volcanic glass. The Al^{3+} released under acidic conditions favors complexation of Al^{3+} with OM leading to formation of organo-Al complexes. In general, silandic Andosols exhibit a neutral to mildly acidic nature, whereas aluandic Andosols have an extremely acid to acid nature.

The content of SRO aluminosilicates in volcanic soils can change over time with a significant influence of temperature, moisture and degree of chemical weathering (Lyu et al., 2018, 2022; Watanabe et al., 2023). Short-range ordered aluminosilicates are formed

Fig. 4 Time course of short-range ordered aluminosilicate content represented by oxalate extractable Si (Si_o) in B horizon soils in Hawaii derived from basaltic volcanic materials under mean annual temperature and precipitation of 16 °C and 2500 mm, respectively. Data taken from Chorover J, Amistadi MK and Chadwick OA (2004) Surface charge evolution of mineral-organic complexes during pedogenesis in Hawaiian basalt, *Geochimica et Cosmochimica Acta*, 68(23): 4859–4876.

from volcanic ejecta and increase until the rapidly weathered primary minerals and volcanic glass are depleted resulting in lower Al^{3+} and H_4SiO_4 activities that are necessary to support their formation (Fig. 4). Later in soil development, the content of SRO aluminosilicates decreases as Ostwald ripening transforms the metastable phases to more thermodynamically stable, crystalline minerals (e.g., kaolinite and gibbsite). Sufficient moisture seems to be critical for the formation of SRO aluminosilicates because most Andisols occur in udic (63%) and ustic (30%) soil moisture regimes (Dahlgren et al., 2004). Soils with less excess precipitation (precipitation minus potential evapotranspiration) contain a limited content of SRO aluminosilicates (Fig. 5a). Dry conditions lead to slower rates of weathering, higher H_4SiO_4 activity due to less leaching, and promotion of crystallization, favoring halloysite formation over allophane and imogolite. Furthermore, high temperature seems to inhibit the formation of SRO aluminosilicates due to enhanced dissolution and precipitation reactions, which results in the preferential formation of more thermodynamically stable crystalline clays that consume metastable SRO aluminosilicates (Fig. 5b).

Other soil-forming factors can influence the formation and distribution of SRO aluminosilicates, primarily by affecting Al^{3+} and H_4SiO_4 activities in the soil solution. Organic matter supplied by vegetation complexes with Al^{3+} in the soil solution results in high organo-Al complexes and opaline silica contents, but little or no allophane in surface horizons (Harsh et al., 2002). Similarly, 2:1 type layer silicates hinder the formation of SRO aluminosilicates, preserving Al^{3+} as hydroxy-Al interlayer polymers. This influence of OM and 2:1 type layer silicates competing for Al^{3+} has been referred to as the ‘anti-allophanic effect’ (Dahlgren et al., 2004), which can lead to the formation of Aluandic Andosols. Other factors include topographic position which controls leaching intensity and residence time of water and, therefore, affects pH and H_4SiO_4 activity; and parent materials that control rates of chemical weathering (e.g., colored vs. non-colored volcanic glasses) and thereby the pH and Al^{3+} and H_4SiO_4 activities in the soil solution.

Short-range ordered aluminosilicates are commonly found in the illuvial horizons of Podzols, in particular Bs horizons rather than organic-rich Bh horizons. In contrast to Andosols, where SRO aluminosilicates precipitate in situ, Si and Al translocate from upper horizons and some may precipitate as SRO aluminosilicates in the illuvial horizons. Several mechanisms are proposed for the translocation of Si and Al and the accumulation of SRO aluminosilicates in subsoil horizons. They include the formation of organo-metal complexes and inorganic colloidal sols (e.g., proto-imogolite) in eluvial horizons that are subsequently translocated to illuvial horizons where they accumulate due to an increase in the metal to OM ratio caused by the addition of metal ions, microbial decomposition of organo-metal complexes, and/or a higher pH range that facilitates the formation of SRO aluminosilicates (Sauer et al., 2007). Alternatively, formation of SRO aluminosilicates in Podzol Bs horizons has been ascribed to in situ weathering as the organic acid acidity and Al^{3+} -complexing organic ligands in surface horizons (e.g., E horizon) are attenuated in the underlying Bh horizons, and carbonic acid becomes the primary proton donor at pH values greater than 5 in the underlying Bs horizons. The dominant mechanism for their translocation and/or accumulation in the subsoil is still open to debate, but may differ according to the soil-forming conditions (Sauer et al., 2007). Soil groups other than Andosols and Podzols can also contain SRO aluminosilicates if the soil-forming factors contribute to the composition of a solution suitable for their formation.

Identification

The poorly crystalline nature of allophane and imogolite defies their easy identification in soils by X-ray diffraction, which is the method of choice for the phyllosilicate clay minerals and many oxides. Rather, a combination of methods is used to identify and characterize these materials, including electron microscopy, selective chemical dissolution, Fourier transform infrared (FTIR) spectroscopy, and differential thermal analysis. Synthetic allophane and imogolite or purified samples from soils can be further

Fig. 5 Relationship between short-range ordered aluminosilicate content represented by oxalate extractable Si (Si_o) vs. excess precipitation (mean annual precipitation – potential evapotranspiration) (a) and vs. mean annual temperature (b) in B horizon soils. The soils were derived from volcanic ejecta in tropical regions having relatively constant temperatures throughout the year. Data taken from Lyu H, Watanabe T, Kilasara M and Funakawa S (2018) Effects of climate on distribution of soil secondary minerals in volcanic regions of Tanzania, *Catena*, 166: 209–219, Lyu H, Watanabe T, Ota Y, Hartono A, Anda M, Dahlgren RA and Funakawa S (2022) Climatic controls on soil clay mineral distributions in humid volcanic regions of Sumatra and Java, Indonesia, *Geoderma*, 425: 116058.

characterized by NMR and X-ray absorption spectroscopy (XAS). Electron microscopy is useful for defining the morphology of individual particles and aggregates of SRO minerals, whereas the other methods give information on the structural and chemical bonding properties.

Allophane and imogolite are not truly non-crystalline or amorphous minerals and do exhibit X-ray diffraction patterns, albeit with diffuse and often weak diffraction peaks. These patterns can be used to identify imogolite and distinguish it from Al-rich (proto-imogolite) allophane (Fig. 6), something not readily accomplished with FTIR. All allophanes, regardless of the Al/Si ratio, display two broad peaks centered around 0.33 and 0.25 nm. The imogolite peaks result from both the long-range order along the longitudinal direction of the imogolite fiber and the close packing structure of fiber bundles.

The clearest way to distinguish between allophane and imogolite is with electron microscopy. Transmission electron micrographs reveal the fibrous bundles of imogolite (Fig. 2) that are readily identifiable even in complex soil mixtures. The imogolite fibers have cylindrical morphology, consisting of a gibbsite-like sheet of aluminum hydroxide octahedra pulled into a cylinder by individual silica tetrahedra. A two-dimensional (2-D) ball-and-stick model in Fig. 7 represents a cross-section of the imogolite tube. Allophane appears amorphous under the electron microscope, appearing gel-like (Fig. 1) or as aggregates of small spherules varying from 3.5 to 5.5 nm. The structure, composition, and morphology of allophane depend largely on its Al/Si ratio.

The quantity of SRO minerals is most commonly estimated by selective dissolution of these materials from soil with some notable cautions. Extraction with acid ammonium oxalate in the dark mainly removes Al and Si from poorly crystalline aluminosilicates and iron (Fe) oxides (i.e., ferrihydrite, nano-crystalline goethite) and Al from complexes with OM (Shang and Zelazny, 2008). The latter Al phase (organo-Al complexes) can be removed by sodium pyrophosphate extraction, which does not dissolve a significant amount of SRO aluminosilicates (Shang and Zelazny, 2008). Thus, the Al/Si ratio of allophane can be estimated from the extracted Al by acid oxalate (Al_o) and pyrophosphate (Al_p) using the formula $(Al_o - Al_p)/Si_o$. Together with sodium pyrophosphate solution to remove organo-Al and -Fe complexes, reductive dissolution with sodium dithionite (e.g., dithionite-citrate bicarbonate (DCB) solution) is applied to remove iron oxides for purifying SRO aluminosilicates; DCB can dissolve a considerable amount of SRO aluminosilicates (Rennert, 2019). It should be noted that the interpretation of extracted Al and Si fractions by these selective extractions has inherent uncertainty, such as Al_o includes Al in the lower-crystallinity iron oxides, the hydroxy-Al interlayer of 2:1

Fig. 6 X-ray diffraction patterns of naturally occurring imogolite and allophane. Reproduced from Wilson MJ (1987) X-ray powder diffraction methods in Wilson MJ, *A Handbook of Determinative Methods in Clay Mineralogy*, Glasgow, UK: Blackie & Son.

Fig. 7 Crystallographic representation of the cross-section of an imogolite tube. Reproduced from Cradwick PD, Wada K, Russell JD, Yoshinaga N, Masson CR and Farmer VC (1972) Imogolite, a hydrated aluminum silicate of tubular structure, *Nature Physical Science*, 240(104): 187–189.

type layer silicates, and Al_p may include small particles of Al hydroxides (colloids) that are not bound to OM (Kaiser and Zech, 1996; Shang and Zelazny, 2008; Rennert, 2019). In addition, Si_o values less than 1 to 2 g kg⁻¹ should not be considered significant because acid oxalate may attack the surfaces of crystalline minerals (Dahlgren, 1994). Once the amount of Al and Si coming solely from SRO minerals has been estimated (e.g., $Al_o - Al_p$ and Si_o), the percentage of allophane and imogolite in the soil can be estimated from:

$$\% \text{ allophane in soil} = Si / (-0.067 Al / Si + 0.27), \quad (1)$$

where Si is the percentage Si from SRO aluminosilicates. This formula is based on an average Al/Si ratio for allophanes found in soils.

Fig. 8 Differential thermal analysis curves of (a) Al-rich allophane and (b) imogolite.

Imogolite can be distinguished from allophane and its concentration in soil estimated by both differential thermal analysis (DTA) and FTIR. Imogolite gives rise to a unique endothermic peak at 400 °C due to structural water loss (Fig. 8). The area of this peak is proportional to the quantity of imogolite in the soil. An FTIR band at 348 cm⁻¹ indicates the structure of both imogolite and Al-rich (proto-imogolite) allophane. This peak can be normalized to provide the quantity of 'imogolite-like structures' in a given soil.

Structure and charge

Infrared and NMR spectra have been instrumental in helping to infer the structure of both imogolite and allophane. The IR band at 940 cm⁻¹ is assigned to the unshared OH (hydroxyl) groups of the orthosilicate groups in imogolite and Al-rich allophane. For all other allophanes, the Si–O (oxygen) stretching band shifts from 975 to 1020 cm⁻¹ as the Al/Si ratio decreases (Fig. 9). This indicates that polymerization of the silicate groups increases with increasing Si concentration. The -79 ppm NMR shift also indicates Si coordinated to three Al–O groups and one OH (Fig. 10). The negative shift in the NMR spectrum as the Al/Si ratio decreases supports increased oxygen-sharing among Si atoms.

Polymerization is accompanied by an increase in tetrahedrally coordinated Al, as indicated by ²⁷Al NMR and XAS spectra, inferring that the Si-rich allophanes have a feldspathoid-like structure. The feldspathoids are network silicates that, like zeolites, are characterized by high structural negative charge density. Such a charge also increases in allophanes as the Al/Si ratio decreases.

In Al-rich allophane and imogolite, the surface charge arises almost exclusively from variably charged aluminol (Al–OH) and silanol (Si–OH) groups. Chemically, the surface charging reactions can be represented as protonation–deprotonation reactions on these groups:

Aluminol groups in gibbsite have no net charge at around pH 9, whereas silanol groups in quartz have a net neutral charge near pH 2. Consequently, it is assumed that the acidic silanol groups contribute a negative charge to the SRO aluminosilicates, and aluminol groups primarily bear a positive charge because, typically, the pH range of soils falls between 3 and 9.

Fig. 11 shows the variable-charge behavior of an Al-rich allophane. The data points represent the amount of Na (sodium) and Cl (chlorine) adsorption determined as a function of pH and ionic strength. The magnitude of adsorption increases with increasing

Fig. 10 The ²⁹Si NMR spectra of three allophanes with decreasing Si/Al molar ratio: A, 0.64; B, 0.59; C, 0.37.

Fig. 11 Ion adsorption and proton charge (σ_H) of synthetic Al-rich allophane in NaCl. Reproduced with permission from Su CM, Harsh JB and Bertsch PM (1992) Sodium and chloride sorption by imogolite and allophanes, *Clays and Clay Minerals*, 40(3): 280–286.

ionic strength, whereas the sign of the charge depends on pH. The pH at which Na and Cl adsorption is equal (i.e., no net surface charge) is known as the point of zero net charge (PZNC). The dotted line in Fig. 11 represents the surface charge determined by adsorption of H^+ and OH^- (σ_H). The pH at which σ_H is zero is known as the point of zero proton charge (PZNPC). The PZNC and PZNPC are equivalent when there is no permanent structural charge in the allophane. The fact that these two are almost equivalent in Fig. 11 also shows that Al is not substituting for Si at tetrahedral sites, and therefore not giving rise to structural charge.

It is evident from Fig. 11 that Al-rich allophane is positively charged in all but calcareous and other alkaline soils. The amount of charge is significant, rivaling smectites in magnitude of charge in both acid and highly alkaline soils. Allophane and imogolite may be among the most important anion exchangers in soils. The use of soils containing allophane as filters for anions such as arsenate, iodide, and technetium has been considered. Silica-rich allophanes, on the other hand, have a significant negative structural charge and will function as important cation exchangers.

Chemisorption and ligand exchange

In addition to the nonspecific cation and anion exchange reactions that occur on positively and negatively charged sites, respectively, metals and ligands can chemisorb to the reactive aluminol and silanol groups. The nonspecific interactions on charged surfaces are characterized by the fact that the ions can be easily exchanged with other ions of like charge from the soil solution. The adsorbed ions remain hydrated (outer-sphere complexes), are kinetically labile, and equivalently balance the surface charge. Chemisorbed ions, on the other hand, bond directly to the aluminol and silanol groups (inner-sphere complexes), are not easily or rapidly exchanged, and do not require an oppositely charged surface group to adsorb. These interactions can govern the transport, stability, and bioavailability of solutes including toxic metals, essential plant nutrients, and soil OM.

Chemisorption of 'heavy' metals such as Zn (zinc), Cu (copper), Pb (lead), Co (cobalt), and Cd (cadmium) generally involves exchange with a proton from a surface silanol or aluminol group. An inner-sphere complex is formed as the metal bonds directly with the oxygen of the surface group. For example, on an aluminol group on allophane:

represents the chemisorption of a divalent metal cation (M^{2+}) where one proton is exchanged. The result, in this example, is a more positively charged surface, a reduction in the mobility of the metal cation, and a decrease in soil pH. Given the high specific surface areas of SRO aluminosilicates and the relatively large number of reactive surface groups, allophane and imogolite can play an important role in metal behavior in soils, even when these minerals are present in low concentration.

The cation exchange behavior of metals depends primarily on their charge and hydrated radius. The selectivity for a negatively charged site increases with charge and decreases with size of the hydrated ion. In the case of the chemisorbed metals, however, the selectivity depends on the nature of the reaction with the aluminol or silanol group. The selectivity series for metals on aluminol groups follows the order:

This series represents the position of the adsorption edge when the amount of metal adsorbed is plotted against pH. It implies that the metals such as Cu and Pb will be chemisorbed to aluminol groups even in acid soils, whereas the alkaline metals like Mg (magnesium) and Sr (strontium) are not chemisorbed in slightly alkaline to acid soils, but only undergo cation exchange. Chemisorption to silanol groups is similar.

Just as allophane and imogolite can be important anion exchangers in soil, they can also chemisorb anions and neutral solutes through ligand exchange:

In the above reaction, an anion (A^-) exchanges with a water molecule, increasing the negative charge on the surface. The anion bonds directly with the surface Al or Si ion, forming an inner-sphere complex. Several solutes are known to chemisorb to allophane and imogolite through ligand exchange, including phosphate, fluoride, selenite, and organic acids.

The sorption of phosphate to SRO minerals has a major effect on the availability of phosphate to crops grown in allophanic soils. Although it was long assumed that this reaction was governed strictly by ligand exchange, it is more likely that phosphate reacts with allophane to form insoluble Al-phosphate phases similar to variscite ($\text{AlPO}_4 \cdot 2\text{H}_2\text{O}$) (Nanzyo, 1987). The strong retention of phosphate may limit fertility of both agricultural and forested soils. Solutions to this potential problem have included not only large applications of inorganic fertilizers, but also the addition of silica and OM to compete with phosphate for reactive sites.

Fluoride (F^-) is strongly adsorbed to both aluminol and silanol groups and results in the release of OH^- by the reactions:

These reactions have been used as a test for the presence of SRO aluminosilicates in soil. The large concentration of reactive groups can easily result in a $\text{pH} > 10$ when a few grams of an allophanic soil are reacted with 0.1 mol L^{-1} NaF, initially at neutral pH. Other SRO minerals, such as ferrihydrite, nano-crystalline goethite and organo-Al complexes, also contribute to this reaction. As in the reaction with phosphate, insoluble metal fluorides can replace allophane.

Reaction with soil organic matter

Soils high in SRO aluminosilicates and other SRO minerals (e.g., ferrihydrite) tend to store large amounts of OM because (i) the environmental conditions favoring their formation ensure relatively large OM input from plants, and (ii) their physical and chemical properties cause a strong affinity for OM. High OM storage capacity and the old C age of Andosols is well-known (Torn et al., 1997). The term 'Andosol' originated in Japan and refers to 'dark soils.' In Andosols and other soils with volcanic parent materials, bulk soil C contents often show a significant positive correlation with pyrophosphate-extractable Al and Fe, and to a lesser extent, with oxalate-extractable Al and Fe (e.g., Percival et al., 2000). Similar positive correlations have been shown for spodic horizons. More recent studies have shown that the Al and Fe which are extractable by these two extractions significantly controlled soil OM content in a wide range of soil types beyond Andosols and Podzols (Ashida et al., 2021; Rasmussen et al., 2018). While the abundance of clay-sized minerals (clay %) has been considered to be the main control on soil OM storage and turnover time, a growing number of studies are showing greater control by SRO mineral abundance, specifically oxalate-extractable Al and Fe, than clay percent in non-arid soils around the world (Rasmussen et al., 2018). Similarly, subsoil OM storage under wetter climates is strongly controlled by SRO mineral abundance due mainly to its sorptive capacity for dissolved organic carbon (Kramer and Chadwick, 2018). Soil C persistence inferred from radiocarbon analysis can be controlled by oxalate- and especially pyrophosphate-extractable Al and Fe contents in soils developed under relatively wet climatic regimes (Lawrence et al., 2021), although the quantitative contribution of specific metal phases such as SRO aluminosilicates remains to be elucidated.

The SRO minerals protect OM from microbial degradation by three general mechanisms as follows. (i) SRO minerals can adsorb large amounts of dissolved organic matter through ligand exchange because of the high specific surface area of allophane and imogolite ($700\text{--}900$ and $900\text{--}1100 \text{ m}^2 \text{ g}^{-1}$, respectively; Harsh et al., 2002) and high surface reactivity (i.e., high density of hydroxyl group per unit surface area). Allophane and imogolite sorb up to $61\text{--}167 \text{ mg C g}^{-1}$ in batch experiments (Inoue and Wada, 1968), which is 1–2 orders of magnitude greater sorptive capacity than well-crystallized silicate clays. (ii) Al and Fe released from SRO minerals (and from other minerals) can be complexed with organic ligands to form mono- or poly-nuclear complexes that are relatively stable against microbial degradation (Boudot et al., 1989; Takahashi and Dahlgren, 2016). Complexation of OM with Al in or released from SRO minerals not only slows OM decomposition but may inhibit the crystal growth of allophane and imogolite (Levard et al., 2012). The formation of organo-Al complexes with little or no SRO aluminosilicates is typically found in the surface horizons with a large OM content and low pH. In this case, it is the Al complexes themselves that impart high reactivity to the soils, such as high phosphate sorption and Al^{3+} solubility. (iii) SRO minerals act as binding agents to form stable aggregates that physically protect OM therein reducing the access of microbes, extracellular enzymes, water and oxygen. Allophanic Andosols have particularly strong physical stability and can form irreversible microaggregates upon dehydration. Across a range of soils, both SRO minerals and OM were co-localized in the meso-density ($1.8\text{--}2.2 \text{ g cm}^{-3}$) fraction, mainly as shaking-resistant, organo-mineral microaggregates where the amounts of residing OM often exceed the level accountable by sorptive stabilization (Wagai et al., 2020). Dissolved Fe, Al, and Si released during mineral weathering can readily interact with dissolved OM to form nano-sized coprecipitates (Tamrat et al., 2019) that contain both sorptive associations and precipitates of organo-metal complexes. In soils, the three mechanisms take place concurrently and their relative importance changes depending on pedogenic conditions (Mikutta et al., 2009).

Aluminum solubility

The activity of Al in soils is an important consideration from an environmental standpoint because Al is toxic to various plant species, especially agricultural crops, and to aquatic organisms. Aluminum activity increases 1000-fold for every unit decrease in pH when Al solubility is controlled by solid phases such as gibbsite, kaolinite, and imogolite. Among the soils for which a solid-phase dissolution mechanism is likely to control Al activity in the soil solution are those containing SRO aluminosilicates. Solution compositions of the B horizons of Podzols, in particular, near equilibrium with an imogolite-like phase are determined in both field and laboratory studies. As mentioned above, the SRO aluminosilicates are metastable with respect to more crystalline minerals such as kaolinite; however, they are persistent in soils and approach equilibrium solubility fairly rapidly.

The dissolution reaction for imogolite can be written as follows:

and the log solubility product ($\log K_{\text{sp}}$) is:

$$\log K_{\text{sp}} = \log(\text{Al}^{3+}(\text{aq})) + 0.5 \log(\text{H}_4\text{SiO}_4(\text{aq})) + 3\text{pH}, \quad (9)$$

where parentheses denote activities.

Aluminum solubility can then be obtained by rearranging:

$$\log(\text{Al}^{3+}) = \log K_{\text{sp}} - 0.5 \log(\text{H}_4\text{SiO}_4(\text{aq})) - 3\text{pH} \quad (10)$$

Thus, the activity of Al^{3+} in a soil solution controlled by imogolite depends negatively on $\text{H}_4\text{SiO}_4(\text{aq})$ activity and pH.

A stability diagram based on some of the published values for imogolite and Al-rich (proto-imogolite) allophane in relation to more crystalline minerals is shown in Fig. 3. The two imogolite lines are from two different investigations. The more stable of the two synthetic imogolites crosses the halloysite stability line at an aqueous H_4SiO_4 activity near $10^{-3.5}$, consistent with the formation of halloysite in soils with higher values. However, the formation of halloysite in preference to imogolite may be kinetic, requiring significant supersaturation. Although the solubilities of these minerals are not well defined, Fig. 3 still shows the metastability of SRO minerals with respect to kaolinite at nearly all H_4SiO_4 activities: the relative stability of gibbsite being higher at low ($\text{H}_4\text{SiO}_4(\text{aq})$) and of halloysite being higher ($\text{H}_4\text{SiO}_4(\text{aq})$).

The kinetics of Al^{3+} and Si release under acidic conditions from allophanic soils containing a variety of SRO aluminosilicates and organo-Al complexes along with pure imogolite gel films from Kitami Pumice beds showed very rapid rates of Al^{3+} and Si release (Fig. 12). The rapid Al^{3+} release kinetics from allophanic soils was attributed in part to a simultaneous Al^{3+} equilibrium that occurs among exchangeable Al^{3+} , organo-Al complexes, SRO minerals and gibbsitic phases that commonly occur in allophanic soils. The rapid release of Al^{3+} from exchange and organo-Al complexes maintains a short-term equilibrium, whereas slower Al^{3+} release from allophane, imogolite and gibbsitic phases maintains the longer-term equilibrium. In soils with the co-existence of imogolite and hydroxy-Al polymers (a gibbsite-like phase) within the interlayer of 2:1 layer silicates, the hydroxy-Al polymer appears to set the ultimate Al^{3+} solubility, whereas the simultaneous Al^{3+} equilibrium with imogolite sets the H_4SiO_4 activity at approximately 10^{-4} (Fig. 3). In soils with considerable 2:1 layer silicates and soil OM, preferential incorporation of Al^{3+} into hydroxy-Al polymers and organo-Al complexes may inhibit the formation of allophane and imogolite, which is a theoretical explanation of the anti-allophanic effect mentioned earlier.

Physical properties

Soils high in SRO minerals generally have very low bulk densities, typically less than 0.85 g cm^{-3} . This is a defining characteristic of Andosols or soils classified as having 'andic' properties (Bäumler et al., 2005). However, individual allophane and imogolite particles have densities of $2.7\text{--}2.8 \text{ g cm}^{-3}$ and $2.6\text{--}2.75 \text{ g cm}^{-3}$, respectively. The low bulk densities result from high microporosity

Fig. 12 The active Al fractions in Andosols appear to form a simultaneous equilibrium between the various solid-phase constituents. Reproduced from Dahlgren RA, Saigusa M and Ugolini FC (2004) The nature, properties and management of volcanic soils in Sparks DL., *Advances in Agronomy*, 113–182.

brought about by particle–particle and aggregate–aggregate associations (Bäumler et al., 2005), and from the strong association between allophanes and soil OM, discussed above. Pure allophane particles form associations with one another that flocculate into microporous aggregates (Fig. 1) when near the point of zero charge or the point where the particles have zero mobility in an electric field. Even in the presence of OM and other minerals, allophanic soils are abundant in highly microporous aggregates that are characterized by strong physical stability (resistant to 5–10 fold greater sonication energy compared to non-andic soils) and having a hierarchical structure (Asano and Wagai, 2014).

The surfaces of allophane and imogolite are assumed to be largely accessible to the soil solution. Specific surface areas determined by a polar molecule such as ethylene glycol monoethyl ether are around $10^3 \text{ m}^2 \text{ g}^{-1}$ (Harsh et al., 2002), which is greater than crystalline clay silicates found in soils including smectites. Specific surface areas of allophanes determined with N_2 (nitrogen) are significantly lower, ranging from 0.3 to $0.6 \times 10^3 \text{ m}^2 \text{ g}^{-1}$ (Vandickelen et al., 1980).

The physical characteristics of SRO minerals and associated OM have a profound effect on soils containing these materials. In addition to the low bulk densities, such soils have unusually large water retention capabilities at both 33 kPa ('field capacity') and 1500 kPa ('permanent wilting point') suction. Saturated water retention has been reported as high as 1.8 kg kg^{-1} . This can be attributed to the high microporosity and leads to favorable conditions for plant growth, particularly in forested soils. Meso- and macro-porosity are also high in andic soils as a result of the granular structure brought about by the aggregation of particles and OM. Consequently, saturated hydraulic conductivity is generally high in allophanic soils.

Both physical and chemical alteration of these soils can change hydraulic conductivity and other physical properties. When soils containing allophane and imogolite are air-dried, there is an irreversible increase in void volume, which results in higher saturated hydraulic conductivity and lower water retention. It is evidently difficult to rehydrate all surfaces and micropores after drying. In the field, mechanical disturbance that enhances drying or disrupts through shearing can lead to significant lowering of soil plasticity, whereas moist andic soils are considered highly plastic. Under the wetting and drying conditions common in cropping systems, these soils tend to resist compaction by machinery and mechanical disruption by rainfall. Finally, adjusting soil pH to values higher or lower than the near-neutral point of zero charge of Al-rich allophanes disturbs particle–particle associations and can reduce hydraulic conductivity by as much as 75% or more.

Implications of short-range ordered aluminosilicates for agricultural productivity

In terms of overall agricultural productivity, silandic (allophanic) Andosols generally have a greater agricultural potential than aluandic (non-allophanic) Andosols. The SRO minerals strongly contribute to several physical, chemical and biological properties of soils that greatly affect agricultural productivity. The SRO aluminosilicate minerals impart excellent physical properties for agricultural production, such as large water retention, high porosity, high permeability, good friability, low bulk density, excellent soil tilth and resistance to soil compaction and erosion. These properties are conducive to plant growth because of the large available water content which facilitates seedling emergence and root penetration. These favorable properties largely result from the formation of stable aggregates facilitated by SRO minerals in association with soil OM.

The chemical properties of Andosols change considerably as chemical weathering progresses and leads to an increasing abundance of SRO minerals. Young volcanic deposits have an abundance of rock-derived nutrients, including P, because of the rapid weathering of glassy and porous volcanic deposits. Nitrogen is generally the most limiting nutrient in young volcanic deposits as N fixation and OM accumulation proceed over the first several hundred years of pedogenesis. As previously discussed, SRO minerals contribute to the accumulation of soil OM and its associated nutrients by chemical and physical stabilization mechanisms. The amount of N released by mineralization is strongly correlated with the amounts of soil OM, especially the fraction defined as the easily decomposable OM pool.

The different charge characteristics between allophanic and non-allophanic Andosols because of their contrasting colloidal mineralogy is the most important factor regulating chemical fertility attributes (Table 1). As weathering progresses and the SRO mineral content increases, strong P retention by SRO minerals may result in P-limitation to several agricultural crops. However, the amount of P adsorbed per mole of active Al was higher in non-allophanic Andosols than allophanic Andosols (0.13 and $0.09 \text{ mol mol}^{-1}$, respectively; Takahashi and Dahlgren, 2016). Silicon, as an important nutrient for crops such as rice (*Oryza sativa* L.) and sugar cane (*Saccharum officinarum* L.), is strongly affected by the colloidal mineralogy. For example, the presence of halloysite generally supports an H_4SiO_4 activity of approximately $10^{-3.5}$ compared to allophane and imogolite which support an H_4SiO_4 activity of about 10^{-4} (Fig. 3). Notably, sheep grazing on silica-rich volcanic soils in New Zealand wears down their teeth much more rapidly than those grazing on non-volcanic soils due to the larger silica content of forage on volcanic soils that abrades the teeth.

Compared to non-allophanic Andosols, allophanic Andosols have only trace amounts of KCl-extractable Al^{3+} and tend to buffer the soil pH(H_2O) values near to 5, resulting in relatively small soluble Al^{3+} concentrations. Consequently, Al^{3+} toxicity is predominantly observed in non-allophanic Andosols containing large amounts of KCl-extractable Al^{3+} derived primarily from 2:1 layer silicates, but not in allophanic Andosols whose major clay minerals are SRO minerals. Larger extractable and soluble Al^{3+} concentrations are shown to inhibit several soil-borne plant pathogens (e.g., common potato scab, rice seedling damping-off disease). Consequently, crops growing on allophanic Andosols are more susceptible to these soil-borne pathogens than non-allophanic Andosols having larger KCl-extractable Al^{3+} concentrations.

Table 1 Comparison of selected soil properties between allophanic Andosols and non-allophanic Andosols.

Property	Allophanic andosols	Non-allophanic andosols
Major clays	Allophane and imogolite	Hydroxy-Al interlayered 2:1 layer silicates
Source of active Al	Allophane and Al-humus complexes	Al-humus complexes
Constant negative charge	None	High
Variable positive charge	Some	None
Soil acidity	Weakly acid	Strongly acid
KCl-extractable Al	Low	High
Al-toxicity	Rare	Common
Consistency—LL, PL, PI ^a	High	Low
Stickiness	None—slightly	Moderately
Plasticity	None—slightly	Moderately
Compaction potential	Slight	Moderate

^aLL is liquid limit, PL is plastic limit; PI is plasticity index.

Outlook

The SRO aluminosilicates have significant influences on environmental and agricultural processes because of their large surface areas and reactive functional groups. Their abundance often covaries with other mineral phases (e.g., organo-metal complexes, amorphous gibbsite, pedogenic Fe oxides) in soil environments, leaving some uncertainty as to their specific independent roles in regulating soil physiochemical properties. Advanced spectroscopic techniques such as scanning transmission electron microscopy with energy dispersive X-ray spectroscopy or electron energy loss spectroscopy may allow their identification and quantification from intact natural soils. Furthermore, as their influence is evident even at small concentrations, such as on OM preservation and phosphate sorption, future investigations on the marginal SRO containing soils, for example, the distributions of SRO minerals in soils other than Andosols and Podzols, their persistence in highly weathered volcanic soils under different temperature and moisture conditions, and their forms in the soils (i.e., imogolite, allophane and proto-imogolite as well as organo-Al complexes) would enhance our understanding of the soil biogeochemical cycles (e.g., C, N, P, 'heavy' metals).

Abstract

Oxide minerals (include oxides, hydroxides, oxyhydroxides and hydrated oxides) are primary and secondary minerals of Si, Fe, Mn, Al and Ti. Secondary oxides, particularly of Fe, Al and Mn, are perhaps the most reactive and important components in many soils due to their large specific surface area and strong sorption capacity for many essential and potentially toxic elements. Iron and Mn oxides also play key roles in many redox reactions and have a major influence on the transformation and availability of organic and inorganic contaminants in soils. This chapter provides an overview of the oxide minerals in soils, with an emphasis on their structure and composition, environmental conditions for their formation and their properties.

Key points

- Metal oxides are important constituents of most soil types.
- Iron, Al and Mn oxides contribute to many chemical reactions in soils.
- In highly weathered soils, Fe oxides control most chemical reactions, also contribute to soil physical and microbial properties.
- Both Fe and Al oxides contribute to the preservation of organic matter in the soil.
- Iron and Mn oxides participate in redox reactions in soils and change the availability of various elements and contribute to the degradation of organic contaminants.

Introduction

The oxide minerals typically present in soils comprise oxides, hydroxides, oxyhydroxides and hydrated oxides of silicon (Si), iron (Fe), manganese (Mn), aluminum (Al) and titanium (Ti). With the exception of the Si oxide quartz and some Ti oxides, which are predominately inherited from parent rock (i.e. primary minerals), most oxides form in soil (i.e. secondary minerals) (Kämpf et al.,

2000). The metal cations, Fe^{2+} , Mn^{2+} , Ti^{4+} , Al^{3+} and Si^{4+} , of oxides are released with the weathering of silicates. The divalent cations Mn^{2+} and Fe^{2+} oxidize and hydrolyze, and precipitate almost exclusively as oxide minerals. The more abundant cations and those with smaller ionic radii, i.e. Al^{3+} and Si^{4+} , have a strong tendency to form secondary aluminosilicate minerals; the formation of Al and Si oxides requires special conditions (Waychunas, 1991). All oxides have low solubility at common soil pH values, and are therefore enriched during pedogenesis. Highly weathered soils in tropical and sub-tropical regions, which have lost a substantial part of their alkali metals, alkaline earths and Si, may contain as much as 50 wt-% metal oxides.

Oxides of Fe, Mn and Al in soil generally exhibit a high specific surface area with reactive surface sites which bind oxyanions strongly (e.g. phosphate (PO_4^{3-}), arsenate (AsO_4^{3-}), selenate (SeO_4^{2-}), molybdate (MoO_4^{2-}) and metal cations (e.g. lead (Pb^{2+}), copper (Cu^{2+}), nickel (Ni^{2+}), zinc (Zn^{2+}), cadmium (Cd^{2+})) thereby affecting the availability and mobility of plant nutrients and toxic metals (Cornell and Schwertmann, 2003). X-ray absorption fine structure (XAFS) spectroscopy has been widely used to probe directly the nature of adsorption reactions of various ions on metal oxides (Ginder-Vogel and Sparks, 2010). Such studies have enabled determination of the exact nature of adsorption complexes, such as, inner- vs. outer-sphere surface adsorption complexes, monodentate or bidentate linkage to the oxide surfaces, mononuclear vs. multinuclear metal surface complexes, and adsorbed vs. co-precipitated metal species (Waychunas et al., 2005).

In the last two decades, it has been recognized that Fe and Al oxides play a crucial role in the stabilization of soil organic matter (SOM) (Kaiser and Guggenberger, 2007; Kleber et al., 2015; Coward et al., 2017; Heckman et al., 2018; Kirsten et al., 2021). Soil organic matter can be stabilized by various processes, such as by forming chemical complexes on the reactive surfaces of Fe and Al oxides, coprecipitation in the mineral structures, forming aqueous complexes and by incorporation within soil aggregates (Kleber et al., 2015).

Some Mn oxides have a strong oxidizing power and may degrade organic pesticides, decrease or increase the toxicity of trace metals, and contribute to the formation of soil organic matter (Grangeon et al., 2020). In contrast, sand-sized crystals of the Si oxide quartz are chemically inert.

The basic structural unit of Fe, Mn, Al and Ti oxides are cationic metal centers bound to six oxygens or hydroxyls. If one drastically reduces the size of the oxygen in relation to the metal cations, this arrangement can be visualized as an octahedron, which is the basic structural unit of these oxides (Fig. 1). The octahedra may be linked to each other in three ways, sharing oxygen corners (1 O), sharing edges (2 O) or faces (3 O). Many oxide minerals like goethite contain only the first two types of connections, while the Fe oxide hematite contains all three. In addition, different structures of Fe, Mn, Al and Ti oxides result from differences in the stacking arrangements of oxygen and hydroxy planes, continuity of the structure in the direction of stacking, and the extent and way the octahedral sites are filled. Silicon is bound to four oxygens, forming a tetrahedron. These tetrahedra are connected via corners only. We will use this polyhedral approach in the text and in figures to introduce the mineral species and highlight their major differences and similarities. For each oxide group, we will give an overview including general formation pathways and their influence on soil properties. This overview is followed by a description of the minerals, their occurrence in soil, and specific conditions of their formation.

Iron oxides

Iron is released by the weathering of Fe(II)-containing silicates (e.g. biotite, pyroxenes, amphiboles, olivines). After oxidation to Fe^{3+} and hydrolysis, most Fe precipitates as Fe(III) oxides. A small proportion of the Fe becomes the structural part of phyllosilicates such

Fig. 1 Linkage of metal octahedra by corners, edges and faces, involving one, two, and three oxygen ligands, respectively. Small structural sub-units are shown of the two most common Fe oxides - goethite and hematite.

Table 1 Iron oxides found in soil environments.

Mineral name Formula	Structural type	Median color Range of hue	Typical crystal shape	Occurrence	Figure
Goethite α -FeOOH	diaspore	strong yellowish-brown 7.3YR – 1.5Y	needles, laths, rod, sub-rounded and rounded plates	Ubiquitous in soils of all climates	2A
Lepidocrocite γ -FeOOH	boehmite	moderate orange 4.9 YR - 7.9 YR	laths	Seasonally anaerobic, noncalcareous soils in cool-temperate climate	2D
Akaganéite β -FeOOH Cl	hollandite	strong brown 1.2 YR - 6.8 YR	spindle-shaped rods	Hot springs, volcanic deposits	2G
Feroxyhyte δ' -FeOOH		brownish orange 2.8 YR - 9.2 YR	spheres		2F
Schwertmannite Fe ₈ O ₈ (OH) ₆ SO ₄	hollandite	dark orange yellow 6.2 YR - 0.3 Y	hedge-hog aggregates	Acid-sulfate springs and mine drainages	2G
Ferrihydrite Fe ₅ HO ₈ · 4H ₂ O		strong brown 3.7 YR - 5.4 YR	plates, needles	Frequent in seasonally wet and/or organic-matter rich soils in cool-temperate climate	2C
Hematite α -Fe ₂ O ₃	corundum	moderate reddish brown 3.5 R - 4.1 YR	hexagonal plates, rods, spheres	Frequent in soils of tropical, subtropical and Mediterranean climate	2B
Magnetite Fe ^{II} Fe ^{III} ₂ O ₄	inverse spinel	dark yellowish brown 6 YR - 9.5YR	laths, cubes	Inherited from magnetite-containing bedrock, microbial origin possible	2E
Maghemite γ -Fe ₂ O ₃	defect spinel	black	octahedra	Common in highly-weathered, tropical and subtropical soils	2E
Green rust Fe ^{II} Fe ^{III} (OH) ₄ Cl	hydrotalcite (pyroaurite)	Bluish-green	plates	Permanently wet subsoils	2H

Bold letters indicate minerals commonly occurring in soil.

as smectite. Under oxic conditions, Fe oxides are very insoluble and are enriched during pedogenesis. They dissolve readily, however, under reducing soil conditions:

This reaction is controlled by microorganisms, which metabolize biomass (represented by CH₂O in the equation above), and transfer freed electrons to Fe³⁺, thereby reducing it to Fe²⁺. Dissolution of Fe oxides is therefore linked to microbial activity. Depending on parent material, degree of weathering and redox conditions, the amount of Fe oxides in soils varies between <1 and > 500 g kg⁻¹. Iron oxides are commonly the strongest pigments in soils, and small quantities may impart vivid colors of red, orange, yellow, brown and even blue-green to soils (Table 1) (Scheinost and Schwertmann, 1999). Depending on pedogenesis, they can occur evenly distributed in the soil matrix, concentrated in certain horizons, or locally enriched as skins, mottles, concretions. Soil horizons indurated by Fe oxides form ferricretes or laterites (Cornell and Schwertmann, 2003).

Soil Fe oxides commonly exist as very small crystals (2–50 nm) and have a large specific surface area (50–450 m² g⁻¹). Due to their circum-neutral point of zero charge (PZC), they contribute to the anion exchange properties of soils. In addition, their surfaces have a strong affinity for oxyanions and many metal cations. In highly weathered soils, there is a significant structural substitution of Al for Fe³⁺, which can be as high as 35 mol% Al in goethite and 18 mol% Al in hematite and maghemite (Singh and Gilkes, 1992). Finally, other metal cations with an ionic diameter similar to Fe³⁺ (e.g., Ni²⁺, Ti⁴⁺, Mn⁴⁺, Co³⁺ (cobalt), Cr³⁺ (chromium), Cu²⁺ (copper), Zn²⁺, V³⁺ (vanadium)) may also partially replace Fe in the crystal structure of Fe oxides, including goethite and hematite (Kaur et al., 2009a, b; Singh et al., 2010; Singh and Gilkes, 1992). Iron oxides interact strongly with organic matter in soils and play an important role in the preservation of organic matter and soil aggregation. Because of these properties, Fe oxides play a significant role in the environmental cycling of plant nutrients such as N and P, of transition metals relevant for metabolic reactions (e.g. Mn, Zn, Co), and of toxic elements like arsenic (As) and uranium (U). The 10 Fe oxide minerals observed in soils or sediments at the Earth's surface, and some of their diagnostic criteria are listed in Table 1. Crystal structures are shown in Fig. 2. Schematic formation and transformation pathways of the most common Fe oxides are shown in Fig. 3.

Goethite (α -FeOOH)

With its strong stability, goethite is the most ubiquitous Fe oxide mineral in soils. In the absence of hematite (see below), its yellowish color is responsible for the yellowish-brown hue of many soils (7.4 YR – 3.5 Y). Goethite formation is favored by the slow hydrolysis of Fe³⁺ hydroxy cations at low temperature (Bigam et al., 2002; Schwertmann and Taylor, 1989). The even distribution of goethite in a soil horizon indicates therefore that the soil has formed under aerated, temperate, humid conditions. The crystal structure of goethite consists of double chains of edge-shared octahedra that are joined to other double chains by sharing corners and by hydrogen bonds (Fig. 2A).

Fig. 2 Crystal structures of common oxide minerals in soils.

Fig. 2—Cont'd

Fig. 2—Cont'd

Hematite ($\alpha\text{-Fe}_2\text{O}_3$)

Soils forming in subtropical or tropical climates often have reddish or even purplish hues (8.0 R – 1.4 Y), derived from blood-red hematite. Hematite usually coexists with goethite, but due to its greater tinting strength it masks the yellowish color of goethite even at low concentrations. Hematite forms by dehydroxylation of ferrihydrite (see below) via a solid-state mechanism or topotactic transformation involving aggregation and crystallization or dehydration with an aqueous-aided 2-D growth mechanism (Fischer and Schwertmann, 1975; Schwertmann and Murad, 1983; Vu et al., 2008). In comparison to goethite, the formation of hematite is favored by neutral pH, increasing soil temperature and decreasing water activity (Schwertmann and Taylor, 1989). The crystal structure of hematite consists of sheets of edge-sharing octahedra. The sheets are connected by edge- and face-sharing octahedra (Fig. 2B). The unique face-sharing arrangement and the resulting proximity of neighboring Fe centers is responsible for the red color of this mineral.

Ferrihydrite ($\text{Fe}_5\text{HO}_8 \cdot 4\text{H}_2\text{O}$)

This meta-stable and poorly crystalline, hydrous oxide of Fe commonly occurs in soils formed under cooler conditions and with changing redox conditions. Its formation is favored by the rapid oxidation and hydrolysis of Fe^{3+} from solution. The transformation into thermodynamically more stable goethite may be hindered by adsorption of silicate, phosphate and organic anions, making ferrihydrite a common constituent of younger soils in association with goethite. The brownish-orange color of ferrihydrite often marks gradients between anoxic and oxic soil regions, e.g. at the transition between water-saturated and aerated soil horizons, and along root channels or other macropores. Ferrihydrite is also responsible for the brownish-orange color in podzol B horizons. Because of the very small crystal size and lack of long-range structural order, ferrihydrite's structural model continues to remain a contentious issue. However, there is mounting evidence that at an early stage the ferrihydrite structure may contain up to 20% Fe in the tetrahedral coordination and the remainder in two different types of octahedral coordination (Fig. 2C) (Funnell et al., 2020; Gilbert et al., 2013).

Lepidocrocite ($\gamma\text{-FeOOH}$)

This vividly orange, less abundant mineral occurs in seasonally anaerobic, clay-rich, carbonate-free soils in humid-cool climates in association with the more stable goethite. Lepidocrocite forms through relatively slow oxidation of Fe^{2+} at low concentrations of carbonate. Its crystal structure contains double chains of octahedra which are joined by shared edges, resulting in corrugated sheets of octahedra. These corrugated sheets are stacked one on top of the other and are held together by hydrogen bonds (Fig. 2D).

Fig. 3 Schematic formation and transformation pathways of common Fe oxides in soils. The precipitation of Fe oxides proceeds from either ferric hydrolysis species (top) or from mixed ferric-ferrous hydrolysis species (bottom). Meta-stable phases are shown in dotted lined boxes. Figure modified after Bigham JM, Fitzpatrick RM, and Schulze DG (2002) Iron oxides. In: Dixon JB and Schulze DG (eds) *Soil Mineralogy with Environmental Application*, pp. 323–366. Madison, WI: Soil Science Society of America; and Cornell RM and Schwertmann U (2003) *The Iron Oxides: Structure, Properties, Reactions, Occurrence and Uses*, 2nd edn. Weinheim, Germany: VCH Verlagsgesellschaft.

Magnetite (Fe_3O_4) and maghemite ($\gamma\text{-Fe}_2\text{O}_3$)

Blackish magnetite is usually inherited from the parent material, but may also form in soil through biotic processes. The brownish-red maghemite is common in soils of tropical and subtropical climates, but also occurs occasionally in temperate soils that have been exposed to forest or heath fires. Maghemite forms either through the oxidation of magnetite, or by heating (300–425 °C) other Fe oxides in the presence of organic compounds (forest fires, campfires, fires in the hearth and other human induced or natural fires). Both magnetite and maghemite have the same inverse spinel structure, with octahedral and mixed tetrahedral or octahedral layers stacked along the crystal direction [111] (Fig. 2E). In magnetite, which contains both Fe^{2+} and Fe^{3+} ions, Fe^{3+} occupies both tetrahedral and octahedral sites, while the larger Fe^{2+} ion occupies octahedral sites only.

Rare Fe oxides

Several minerals have rarely or never been observed in soils. They may form in extreme natural environments (akaganéite, schwermannite), in polluted surface waters (schwermannite, feroxyhyte), or transform rapidly into more stable phases (green rust). *Feroxyhyte*, $\delta'\text{-FeOOH}$, was observed in rusty precipitates of rapidly flowing Fe^{2+} -containing water which was quickly oxidized. It consists of sheets of edge-sharing octahedra (Fig. 2E).

Akaganéite ($\beta\text{-FeOOH Cl}$) has been found in environments with large chloride concentrations (0.1 M), low pH (3–4), and high temperature (60 °C), e.g. in hot springs, inland acid sulfate soils and volcanic deposits (Bibi et al., 2011; Bigham et al., 2002). Akaganéite consists of 2×2 channels (referring to the width of the channels in octahedral units) formed by edge-sharing double chains (Fig. 2G). These tunnels are 0.5 nm in cross section and contain Cl^- (chloride) ions that stabilize the structure.

Schwermannite, $\text{Fe}_8\text{O}_8(\text{OH})_6\text{SO}_4$, is isostructural with akaganéite, but SO_4^{2-} occupies the tunnels (Fig. 2G). Schwermannite has been found in strongly acid sulfate waters associated with mining activities (acid mine drainage) or pyritic rock outcrops (Bigham et al., 1990, 2002).

Green rust, also called fougérite $[\text{Fe}^{\text{II}}_{1-x}\text{Fe}^{\text{III}}_x(\text{OH})_2]^{x+} \cdot (x/n)\text{A}^{n-} \cdot m\text{H}_2\text{O}$ (A: anions like Cl^- , NO_3^-), has been observed rarely in reducing, weakly acid to weakly alkaline subsoils. Its greenish-blue color changes rapidly to yellowish brown on exposure to the air,

indicating its instability against oxidation. Green rust consists of sheets of edge-sharing octahedra, which are occupied by both Fe^{2+} and Fe^{3+} . The resulting positive charge of the layers is balanced by hydrated anions in the interlayer space (Fig. 2H). Because of its anion exchange capacity, redox reactivity and high surface area, even small amounts of green rust may play an important role in aquifers and the vadose zone. Since the mineral forms as a metastable corrosion product of metallic iron under anaerobic conditions, green rust is also relevant for barriers of scrap iron engineered to clean up groundwater.

Manganese oxides

Manganese is released by weathering of Mn(II)-containing silicates (biotite, pyroxenes, amphiboles). After oxidation of the soluble Mn^{2+} to Mn^{3+} and Mn^{4+} , brownish-black Mn oxides of low solubility precipitate, which re-dissolve only under reducing soil conditions. The reaction equation assuming an Mn(IV) oxide can be written in an analogous way to the dissolution of Fe oxides

As for the Fe oxides, dissolution depends on microbial activity. While oxidation of Mn^{2+} is catalyzed by mineral surfaces, microbial oxidation seems to be the more dominant process in soil environments. Therefore, both formation and dissolution of Mn oxides are intimately linked to microbial activity in soils (Banfield and Nealson, 1998; Grangeon et al., 2020).

Manganese oxides may occur evenly distributed in the soil matrix like the stable Fe oxides goethite and hematite. With their relatively small concentration (about 1/50 of the concentration of Fe oxides) and their poor crystallinity, however, they are extremely difficult to identify. Therefore, most soil Mn oxides have been identified in local enrichments, like black coatings on peds, dendrites or nodules, which form along redox gradients. The blackish colors of Mn oxides are often separated from the brownish-orange color of Fe oxides (ferrihydrite) by extending further toward the higher redox potential, indicating the greater mobility of Mn^{2+} compared to Fe^{2+} .

Manganese oxides can accumulate a wide range of other elements such as lithium (Li), barium (Ba), As, Pb and almost all 3d (group 3 in the d-block of the periodic table) transition metals. These elements are either part of the crystal structure, or they are tightly adsorbed to the large surface area of Mn oxides. Manganese oxides have an oxidizing potential stronger than that of O_2 . Therefore, they can oxidize inorganic ions such as Co^{2+} , Cr^{3+} and As^{3+} , thereby either increasing (e.g., Cr^{6+}) or decreasing (e.g., Co^{3+} , As^{5+}) their mobility and toxicity. They are also able to oxidize organic molecules, thereby enhancing the degradation of anthropogenic compounds such as pesticides. Furthermore, Mn oxides catalyze condensation reactions like the Maillard reaction. Hence, Mn oxides may play an important role in the abiotic formation of humic substances.

In spite of their importance for the geochemistry of metals and carbon, the knowledge of Mn oxides and their formation in soils remains relatively poor. Manganese oxides often occur as nanoparticles, typically in the 5–100 nm size range, with poor crystallinity and small concentrations, all of these and the occurrence of Mn in different valence forms complicates the determination of their exact mineralogical nature in soils (Bargar et al., 2009; Grangeon et al., 2020). The structures of Mn oxides have been determined using synchrotron-based X-ray diffraction and XAFS spectroscopy (Silvester et al., 1997; Post et al., 2002). More recently, Raman spectroscopy has been shown to be an effective technique for routine identification and characterization of layer- and tunnel-structure Mn oxide phases (Post et al., 2020, 2021). Manganese can occur in Mn(II), Mn(III), and Mn(IV) oxidation states depending on the Eh/pH conditions prevailing in the soil environment. Iltona et al. (2016) developed a procedure using X-ray photoelectron spectroscopy (XPS) to quantify the Mn oxidation state in hydrous multivalent Mn oxides such as birnessite.

Based on the arrangement and linkage of their metal octahedra, the Mn oxides have been categorized into three major groups: (1) phylломanganates or layer structures, (2) tectomanganates or tunnel structures, and (3) chain structures. The most common Mn oxide minerals in soils are listed in Table 2, their crystal structures are shown in Fig. 2 (Waychunas, 1991).

Phylломanganates (layer structures)

Phylломanganates are commonly observed after microbially catalyzed oxidation of Mn^{2+} and they are ubiquitous in soils.

Birnessite forms in a wide variety of soils. It consists of sheets of edge-sharing MnO_6 octahedra with vacancies. The resulting negative layer charge is compensated by cations like Na^+ , K^+ , Ca^{2+} , Mg^{2+} , and Mn^{2+} , which may cover the vacancies. The interlayer region contains water, resulting in a d-spacing of 7 Å (Fig. 2I). Three other minerals, vernadite, chalcophanite and busserite, are structurally very similar to birnessite.

Vernadite is frequently observed as an initially amorphous oxidation product of microorganisms and has been found in soils and in freshwater lakes. Its structure may be similar or identical to turbostratic H^+ -birnessite.

Chalcophanite has been observed in Zn-contaminated soils. In comparison to birnessite, it has a greater number of vacancies that are covered by Zn in octahedral or tetrahedral coordination (Fig. 2J).

Busserite forms in hydrothermal environments. Compared with the former phyllosilicates, it has a larger d-spacing of 10 Å, probably due to a larger amount of interlayer water. After dehydration, busserite transforms into birnessite.

Lithiophorite (a basic oxide of Li, Mn and Al) has been frequently identified in soils. Its layer structure consists of sheets of edge-sharing MnO_6 octahedra which alternate with sheets of (Al, Li)(OH)₆ octahedra (Fig. 2F). The cation sites in the Mn—O octahedral sheet are occupied with Mn^{4+} and Mn^{3+} . The net negative layer charge is counterbalanced by the positive charge of the (Al, Li)-OH octahedral sheets. Lithium is frequently replaced by Ni, Cu and Zn, while Co substitutes for Mn within the octahedral Mn sheets.

Table 2 Manganese oxides found in soil environments.

Mineral name (synthetic equivalent)	Formula	Structural type	Figure
Birnessite	$(\text{Na,Ca,Mn}^{2+})\text{Mn}_7\text{O}_4 \cdot 2.8 \text{ H}_2\text{O}$	layer structure	2I
Vernadite	$\text{MnO}_2 \cdot n\text{H}_2\text{O}$	layer structure	—
(δ - MnO_2)			
Chalcophanite	$\text{ZnMn}_3\text{O}_7 \cdot 3 \text{ H}_2\text{O}$	layer structure	2I
Buserite	$\text{Na}_4\text{Mn}_{14}\text{O}_{27} \cdot 21 \text{ H}_2\text{O}$	layer structure	—
Lithiophorite	$\text{LiAl}_2\text{Mn}_2^{4+}\text{Mn}^{3+}\text{O}_6(\text{OH})_6$	layer structure	2F
Todorokite	$(\text{Na,Ca,K})_x(\text{Mn}^{4+}\text{Mn}^{3+})_6\text{O}_{12} \cdot 3.5 \text{ H}_2\text{O}$ ($x = 0.3\text{--}0.5$)	3×3 tunnel	2J
Romanechite	$\text{Ba}_{0.66}(\text{Mn}^{4+}\text{Mn}^{3+})_5\text{O}_{10} \cdot 1.34\text{H}_2\text{O}$	3×2 tunnel	—
Hollandite	$\text{Ba}_x(\text{Mn}^{4+}\text{Mn}^{3+})_8\text{O}_{16}$ ($x = 1$)	2×2 tunnel	2G
(α - MnO_2)			
Cryptomelane	$\text{K}_x(\text{Mn}^{4+}\text{Mn}^{3+})_8\text{O}_{16}$ ($x = 1.3\text{--}1.5$)	2×2 tunnel	2G
Coronadite	$\text{Pb}_x(\text{Mn}^{4+}\text{Mn}^{3+})_8\text{O}_{16}$ ($x = 1\text{--}1.4$)	2×2 tunnel	2G
Pyrolusite	MnO_2	rutile	2K
(β - MnO_2)			
Manganite	MnOOH	rutile	2K
(γ - MnOOH)			
Ramsdellite	MnO_2	diaspore	2A
Groutite	MnOOH	diaspore	2A
(α - MnOOH)			
Feitknechtite	MnOOH	boehmite	2D
(β - MnOOH)			
Hausmannite	Mn_3O_4	inverse spinel	2E

Bold letters indicate minerals commonly occurring in soil.

Asbolane forms in soils with large Co and Ni concentrations. Its structure is very similar to that of lithiophorite, with alternating sheets of Mn^{4+} -O octahedra and Co—Ni—OH octahedra (Fig. 2F). The Co—Ni sheet may be discontinuous (island-like).

Tectomanganates (tunnel structures)

Tectomanganates are formed from double or triple chains of MnO_6 octahedra, that form tunnels (or channels). These tunnels are occupied by large foreign cations and water molecules.

Todorokite is the most frequently observed soil tectomanganate. It consists of triple chains of edge-sharing MnO_6 octahedra linked to form large 3×3 tunnels. These tunnels contain Na, Ca, K, Ba, strontium (Sr) and water molecules (Fig. 2J). The occurrence of variable tunnel widths (3×2 , 3×3 , 3×4 , and 3×5) observed in HRTEM images suggests that todorokite represents a family rather than a single mineral.

Hollandite, *cryptomelane*, and *coronadite*, sometimes grouped as α - MnO_2 , have rarely been observed in soils. They consist of double chains of edge-sharing MnO_6 octahedra linked to form 2×2 tunnels (Fig. 2G). The tunnels contain water molecules together with cations, which are primarily Ba^{2+} in hollandite, K^+ in cryptomelane, and Pb^{2+} in coronadite. Natural samples usually contain a variety of cations in the tunnels. The large cations are located at specific tunnel sites, and their presence is necessary to prevent the structure from collapsing. The charges of the tunnel cations are balanced by the substitution of Mn^{4+} by Mn^{3+} in the tunnel walls.

Chain structures

Manganese oxides of this group have been synthesized in the laboratory at ambient temperature and pressure, and at moderately alkaline pH. However, they have rarely been observed in soil. Pyrolusite (MnO_2) and Manganite (γ - MnOOH) consist of single chains of edge-sharing MnO_6 octahedra which form 1×1 pseudo-tunnels (Fig. 2K). Ramsdellite (MnO_2) and Groutite (α - MnOOH) are isostructural with goethite (Fig. 2A); Feitknechtite (β - MnOOH) has a structure similar to lepidocrocite (Fig. 2D). Hausmannite (Mn_3O_4) has a disordered-spinel structure analogous to magnetite (Fig. 2E).

Aluminum oxides

In contrast to Fe and Mn, most Al released by the weathering of Al-containing silicates is taken up by secondary, pedogenic phyllosilicates. As long as the Si concentration in the soil solution is $>0.5 \text{ mg L}^{-1}$, the formation of phyllosilicates out-competes the formation of Al oxides. Furthermore, the complexation of Al^{3+} by organic matter prevents Al oxide precipitation in soils. Therefore, Al oxides are commonly observed only in organic matter-poor soils of tropical and subtropical climates, where intense weathering

Table 3 Aluminum oxides found in soils.

<i>Mineral</i>	<i>Formula</i>	<i>Figure</i>

Corundum	$\alpha\text{-Al}_2\text{O}_3$	2B

Bold letters indicate minerals commonly occurring in soil.

causes secondary phyllosilicates to dissolve and Si is lost by leaching. The (colorless) Al oxides are either evenly distributed within the soil matrix or enriched in concretions (pisolithes). Horizons cemented by Al oxides are called alcretes.

Aluminum oxides have a large specific surface area (up to $600 \text{ m}^2 \text{ g}^{-1}$), a high PZC (pH 8–10), and a pH-dependent surface charge. Similar to Fe and Mn oxides, Al oxides strongly adsorb heavy metals (Cu, Pb, Zn, Ni, Co, Cd) and anions (phosphate, silicate, molybdate, sulfate, catechol) by forming inner-sphere complexes (Hsu, 1989; Huang et al., 2002). The adsorption is related to the reactive surface area (singly coordinated OH^- groups at crystallite edges) rather than the total surface area. Aluminum oxides, in addition to Fe oxides, are responsible for soil aggregation of Ferralsols (Oxisols) and Alisols or Acrisols (Ultisols), but the mechanisms of aggregation are unclear. Aluminum oxides have a low solubility at slightly acidic and neutral pH, but at low pH soluble species form, particularly Al^{3+} , that are toxic to plants and animals. These soluble species affect food production on naturally acidic soils and contribute to forest decline in areas influenced by acid rain.

Of the six different Al oxide minerals, predominately gibbsite and, less commonly, boehmite, nordstrandite and bayerite form under soil conditions (Table 3). Diaspore and corundum are occasionally found in bauxite deposits, but are rare in soils. Aluminum also forms highly reactive, poorly crystalline precipitates and colloids (Huang et al., 2002).

Gibbsite

Of the four Al(OH)_3 polymorphs (Table 3), gibbsite ($\gamma\text{-Al(OH)}_3$) is most common in soils. It consists of sheets of edge-sharing octahedra stacked along the c axis (Fig. 2L). Only two-thirds of the available octahedral sites are filled with Al^{3+} ions analogous to the dioctahedral sheets of phyllosilicate minerals. In soil, gibbsite forms thick, platy crystals. In saprolites, feldspars (plagioclase) may transform directly into gibbsite while maintaining the original shape of feldspar crystals (pseudomorphs).

Gibbsite is found in Ferralsols (Oxisols) on old, stable upland landscapes in association with Fe oxides (goethite, hematite) and kaolinite. Intense weathering and leaching under humid tropical and subtropical climates over long periods of time (millions of years) have depleted these soils of the alkali metals, alkali earth metals and Si, thereby enhancing the formation of gibbsite. The gibbsite content of Ferralsols may be as large as 600 g kg^{-1} , but some Oxisols do not contain gibbsite at all. In Alisols or Acrisols (Ultisols) and Cambisols or Inceptisols of tropical to temperate climates, gibbsite is derived from the underlying saprolite, which has formed by weathering of igneous and metamorphic rocks. The gibbsite content generally decreases from the saprolite to the soil surface. Finally, gibbsite has been observed in Andosols or Andisols, where it formed from the rapid weathering of volcanic ash. Although these soils are often very young (hundreds of years) and Si-rich, sufficient Si has been leached locally to explain the formation of gibbsite.

Gibbsite formation is conditioned by the intensity of leaching which, in turn, is affected by rainfall, temperature, parent rock, topography, ground-water table, vegetation, and time. Environments with warm temperatures, high rainfall and free drainage favor desilication and leaching of ions, as well as mineralization of organic matter. Anions such as sulfate, carbonate, phosphate and silicate, together with organic ligands like citric, malic, tannic, aspartic, and fulvic acids have a strong affinity for Al^{3+} , and they may interfere with the crystallization of Al(OH)_3 . This explains why there is either none or only small amounts of gibbsite in the A horizon of acidic soils with considerable organic matter and exchangeable Al, while it is found in greater quantities in deeper horizons. However, gibbsite may also decrease with soil depth. A possible explanation is an inverse gradient of Si(OH)_4^0 (silica) activity: rain water infiltrating at the soil surface is not yet in equilibrium with silicates and therefore has a lower silica activity than the soil water at a greater depth, which has had more time to equilibrate. The heterogeneous distribution of gibbsite in a landscape may be explained similarly by the silica activity of percolating waters.

Rare Al oxide minerals

The difference between gibbsite and its other polymorphs bayerite, nordstrandite and doyleite consist of a slightly different arrangement of hydroxyl groups. While gibbsite formation is favored by the slow hydrolysis of Al and by a pH <6, nordstrandite and bayerite form at neutral to alkaline pH under fast hydrolysis. Correspondingly, their rare occurrences are related to limestone materials. Boehmite ($\gamma\text{-AlOOH}$), which is isostructural with lepidocrocite (Fig. 2D), has been identified in lateritic materials and in bauxites. It may form from gibbsite by diagenesis or hydrothermal alteration. The oxyhydroxide diasporite ($\alpha\text{-AlOOH}$) is

isostructural with goethite (Fig. 2A). It has been identified as a surface weathering product formed by the desilication of kaolinitic clay. The rarely found oxide corundum (α - Al_2O_3), which is isostructural with hematite (Fig. 2B), may be derived from corundum-containing parent rock, or form by heating of the soil by bush fires.

Aluminum hydrolysis and poorly crystalline Al hydroxides

The Al^{3+} cations released from Al-bearing minerals are initially coordinated with 6 water molecules forming the hexaquo complex $\text{Al}(\text{H}_2\text{O})_6^{3+}$. This hexaquo complex hydrolyses in several steps, the first and most important one in the soil solution is

At higher Al^{3+} or OH^- concentrations, the mononuclear complexes start to polymerize to form polynuclear species. The smallest unit identified so far is $\text{AlO}_4\text{Al}_{12}(\text{OH})_{24}(\text{H}_2\text{O})_{12}^{7+}$. This so-called Al_{13} or Keggin polymer consists of a highly symmetrical, tetrahedrally coordinated Al center enclosed in a cage-like structure of 12 octahedrally coordinated Al centers. Further polymerization of this colloidal species leads to the precipitation of a poorly crystalline solid phase.

Silicon oxides

Silicon oxides differ from the oxides of Fe, Mn and Al in several aspects. The most prevalent Si oxide, quartz (SiO_2), is a primary mineral in many rocks, contributing $\sim 120 \text{ g kg}^{-1}$ to the average composition of the Earth's upper mantle. In soils, dissolved Si associates with Al to form aluminosilicate clay minerals. However, secondary Si oxide precipitates may also form in soil, sometimes to such an extent that they cement the soil matrix to form duricrusts and silcretes. Primary quartz crystals are very pure, hard and recalcitrant, and occur in soil as large particles (sand). Their small specific surface area, their small number of reactive bonds at the surface, and the lack of isomorphic substitution makes them chemically very inert. Quartz has the lowest ion exchange capacity ($\text{CEC} = 1\text{--}2 \text{ cmol}_c \text{ kg}^{-1}$) of all soil minerals. The solubility of Si oxides is low at usual soil pH (2–8), but strongly increases at pH >8. The main soluble species, $\text{Si}(\text{OH})_4^0$ (monosilicic acid), is taken up by higher plants, especially grasses and paddy rice, to increase the mechanical strength and resistance against fungal pathogens and herbivores, and is later recycled back into the soil as biogenic opal. Radiolarians, diatoms, silica sponges and cyanobacteria are known to accumulate large amounts of Si oxides in fresh and marine waters, and microorganisms may exert a similar function in soils, competing with the inorganic formation of aluminosilicate clay minerals.

The Si oxides are tectosilicates. The repeating unit is a SiO_4 tetrahedron in which each O is linked to Si atoms of adjacent tetrahedra, forming a strong three-dimensional framework structure. This contrasts with the Fe, Al, Mn and Ti oxides in which the basic unit is a cation in an octahedral coordination. In the following, only α -quartz, α -cristobalite and opal, which commonly occur in soil, will be described (Table 4) (Heaney et al., 1994; Monger and Kelly, 2002).

Quartz and cristobalite

The α -Quartz consists of paired helical chains of corner sharing SiO_4 tetrahedra that spiral along the c-axis. The intertwined chains produce open, hexagonal channels (Fig. 2N). In cristobalite, the tunnels are larger (Fig. 2O), and the density is smaller (2.32 g cm^{-3}) compared to quartz (2.65 g cm^{-3}).

Quartz is ubiquitous in soil environments, while cristobalite is restricted to soils developed from volcanic materials. The quartz in soils is mainly a primary mineral, inherited from the parent material. In soil solution, quartz may form from soluble $\text{Si}(\text{OH})_4^0$ by polymerization, precipitation of amorphous, hydrous SiO_2 , that slowly transforms into crystalline quartz. Direct precipitation from solution seems to be unlikely. Quartz is generally concentrated in the sand and silt fractions of soils, with a lower frequency in the coarse-clay fraction ($0.2\text{--}2 \mu\text{m}$). Quartz may comprise >90% of the inorganic fraction of Quartzipsamments. By contrast, highly

Table 4 Silicon oxides found in soils.

Mineral	Formula	Structural type	Occurrence	Figure
α-Quartz	SiO_2		ubiquitous	2N
α -Tridymite	SiO_2			–
α-Cristobalite	SiO_2		volcanic deposits	2O
Opal-C	$\text{SiO}_2 \cdot x\text{H}_2\text{O}$	well-ordered α -cristobalite	volcanic deposits	–
Opal-CT	$\text{SiO}_2 \cdot x\text{H}_2\text{O}$	disordered α -cristobalite and α -tridymite	cherts, porcelanites, fossil wood, silcretes	–
Opal-A	$\text{SiO}_2 \cdot x\text{H}_2\text{O}$	nearly amorphous	biogenic ubiquitous; inorganic in strongly weathered soils, duripans, silcretes	–

Bold letters indicate minerals commonly occurring in soil.

weathered and leached Oxisols have only very small amounts of quartz left. The solubility of quartz ranges from 1 to 4 mg L⁻¹ Si depending on particle size.

Opal

Opal is classified into three structural groups, opal-C (well-ordered α -cristobalite), opal-CT (disordered α -cristobalite, α -tridymite) and opal-A (highly disordered, nearly amorphous). Opal contains 40–90 g kg⁻¹ water, and the specific gravity ranges from 1.5 to 2.3 g cm⁻³.

Opal-C and α -cristobalite occur in Andepts and other soils derived from volcanic material. Opal-CT has been identified in soils derived from bentonites, siliceous shales, and indurated silicates. Opal-CT is also a primary constituent of many cherts, porcelanites, fossil wood, silcretes, and some duripans. Opal-A may form by both organic and inorganic processes in pedogenic environments. Biogenic opal-A originates from Si accumulated by plants and aquatic organisms, and thus occurs under a wide range of environmental conditions. Biogenic opal is an almost ubiquitous constituent of soils. Opal phytoliths are mostly derived from grasses, while sponge spicules, diatoms, and radiolaria, which form in aquatic environments, may reach soils by weathering of sedimentary bedrocks. Amounts of opal phytoliths in soils commonly range from <1 to 30 g kg⁻¹, usually occurring in the 5–50 μ m size fraction, and decreasing with soil depth. Inorganic opal-A forms from supersaturated soil solutions. It occurs as nodules and as the primary cement of indurated soil horizons (duripans) and silcretes.

At ambient temperature and neutral pH, the solubility of amorphous Si is approximately 50–60 mg Si L⁻¹, and therefore much higher than that of quartz. The presence of organic molecules greatly enhances the rates of dissolution of Si oxides. Coatings of chemisorbed Al and Fe, however, reduce the rates of dissolution rates. Oxides of Fe and Al, by acting as a sink for soluble Si, greatly increase the rates of dissolution of amorphous Si oxides and of reactive, uncoated quartz surfaces. Dissolution (weathering) of Si oxides, which starts below approximately 3 mg of Si L⁻¹, is induced by the reduction of Si levels in the soil solution by leaching and plant uptake.

Titanium oxides

Titanium oxides are common in many igneous and metamorphic rocks and sediments. Because of their resistance to weathering, they are often inherited in soils. However, Ti oxides also form in soil after weathering of less resistant, Ti-bearing minerals (biotite, amphiboles). Titanium oxide minerals are relatively heavy (density > 2.9 g cm⁻³). Their concentration in soils is usually small; because of their small specific surface area, they do not contribute significantly to soil reactivity. In tropical soils only, where they become increasingly enriched during pedogenesis, has some influence on phosphate and arsenate retention has been observed. Old sand dunes, e.g., in the southeastern United States or Senegal, may contain enough Ti oxides to be mined as a commercial source for TiO₂, which is used to produce white paint. Because of their recalcitrant nature, Ti oxides can be used as reference minerals to study weathering and soil genesis.

Titanium occurs primarily in octahedral coordination, and like the Fe and Mn oxides, the structures of the various Ti oxide minerals can be described in terms of the different arrangements of the Ti-containing octahedra. The principal Ti minerals are listed in Table 5 (Fitzpatrick and Chittleborough, 2002).

Rutile (TiO₂) is isostructural with pyrolusite and manganite, consisting of single chains of edge-sharing TiO₆ octahedra (Fig. 2K). Rutile is a common residual mineral occurring in the sand and silt fractions of a variety of soils. Anatase consists of edge and corner-sharing octahedra that outline a three-dimensional framework, rather than distinct chains (Fig. 2M). The platy crystals found in soils are believed to be a weathering product of titanite (CaTiSiO₅) and Ti-bearing silicates. Anatase is easily synthesized at room temperature. Ilmenite (FeTiO₃) is almost isostructural with hematite, with one half of the octahedral centers occupied by Fe²⁺, the other half by Ti⁴⁺ (Fig. 2B). By oxidation of the structural Fe²⁺ to Fe³⁺, ilmenite weathers to pseudorutile (Fe₂O₃·nTiO₂·mH₂O; 3 < n < 5 and 1 < m < 2), a structurally disordered and poorly characterized mineral. Pseudorutile has been widely identified in

Table 5 Titanium oxides found in soils.

<i>Mineral</i>	<i>Formula</i>	<i>Figure</i>
Rutile	TiO ₂	2K
Anatase	TiO ₂	2M
Ilmenite	Fe ²⁺ TiO ₃	2B
Pseudorutile	Fe ₂ O ₃ ·nTiO ₂ ·mH ₂ O (n = 3–5, m = 1–2)	—
Ulvöspinel	Fe ₂ TiO ₄	2E
Titanomagnetite	Fe _{3–x} Ti _x O ₄	2E
Titanomaghemite	Fe _{2–x} Ti _x O ₃	2E

Bold letters indicate minerals commonly occurring in soil.

soils, primarily as the weathering product of ilmenite. Ilmenite itself is relatively unstable in soils, because it weathers easily to pseudorutile and mixtures of rutile, anatase, and Fe oxides.

Titanomagnetites ($\text{Fe}_{3-x}\text{Ti}_x\text{O}_4$) are solid solutions of magnetite with ulvöspinel (Fe_2TiO_4), with Ti^{4+} occupying only octahedral sites of the magnetite structure (Fig. 2E). Their formation is probably related to that of magnetite (see there). Titanomaghemitites ($\text{Fe}_{2-x}\text{Ti}_x\text{O}_3$) form by weathering of titanomagnetites. Their composition is between those of magnetite, maghemite and ulvöspinel. Many aspects of the Ti oxides, such as whether the minerals are relict or pedogenic, and the conditions responsible for their weathering and formation in soils, are still unresolved.

Conclusions and the future

Metal oxides are important soil components, and they often dominate the clay fraction of highly weathered soils in tropical and sub-tropical regions. Iron oxides are the most abundant and frequently occurring metal oxides in soil environments, and they exert a significant influence on the chemical, physical and microbial properties of soils. The structure and formation of metal oxides, which exist in small amounts in soils (e.g., Mn and Ti oxides) have not been studied adequately and remain poorly understood.

Metal oxides, particularly Fe, Al and Mn oxides, exist in poorly crystalline to well crystalline forms that range from nano- to micro-sized particles in soils. These oxides contribute significantly to the sorption of nutrients and contaminants in soil environments. In the last two decades the role of Fe and Al oxides in the preservation of soil organic carbon (SOC) has been recognized, however, the actual mechanisms and stability of the SOC associated with oxides are not well understood. Soil microbes are involved in the formation and dissolution of some of the Mn and Fe oxides, and many of the processes involved in their crystallization and dissolution are not well understood in soil environments, particularly under field conditions.

There is a good understanding of the sorption behavior and mechanisms of ions of nutrient elements and contaminants on the synthetic or pure metal oxides, however, limited research has been done on the interactive behavior of metal oxides in soil systems involving sorption of ions that exist in mixtures. Thus, the modelling predictions in the soil systems remain uncertain.

Abstract

Soil morphology focuses on standardizing descriptions of soil properties and features in the field. Although often qualitative and empirical, these descriptions aid in the interpretation of soil properties measured in the laboratory through chemical, biological and physical methods. Soil morphology is also one of the foundations for soil taxonomy. In the past, soil morphology has relied mostly on human sensors to detect features like color, consistency, texture, horizons, roots, pores, etc. Developments in digital sensors, remote and proximal, now offer more sophisticated tools to describe soils. In this chapter, we provide brief descriptions of the morphological concepts and tools used by soil scientists.

Key points

- Soil morphology is used to describe soil properties and features in the field using simple tools and preceptory human sensors.
- Soil micromorphology uses tools such as microscopes to characterize features like pores, mineralogy, etc.
- Proximal sensors and soil digital morphometry bring together morphology, micromorphology and analytical chemical, physical and biological methods using software and machine learning techniques.

Introduction

Soil morphology is defined as the branch of soil science that deals with the description of in situ spatial organization and physical properties of soil regardless of potential applications (Wilding et al., 1983). Precise descriptions that use standard terminology are needed in all areas of soil science. The basic terminology has been developed over the past 50 years and continues to expand. Prior to the use of standard terminology, soils were described as clayey, sandy, stony, sedimentary, saline, marshy, dry or moist, heavy or light, soft or compact, fatty, friable, or lean. Soil horizons were described by terms such as 'gray watery sand' or 'rusty brown clay' (Buol et al., 1997; Soil Science Division Staff, 2017). While these terms illustrate a fundamental understanding of soil properties, they do not impart any specific knowledge about the soils in question and cannot be compared to descriptions of other soils by other scientists. An objective, complete description of the soil is essential because it serves as a basis for soil identification, classification, correlation, mapping, communication, and interpretation (Soil Survey Staff, 2010; U.S. Department of Agriculture, Natural Resources Conservation Service, 2022).

The basic tools used by field soil morphologists are very simple and usually include a knife, tape measure, water bottle, Munsell color book, 10× hand lens, 10% HCl (hydrochloric acid), a clinometer or Abney level, and often GPS to locate the sites in the geographic domain. The development of proximal sensors has provided additional tools for soil scientists in the field that has led to the emergence of digital soil morphometrics (Hartemink and Minasny, 2014). One such tool is a handheld portable X-ray diffractometer (pXRF), used to map the distribution of metals in the soil profile. Another sub-discipline of soil science, digital soil morphometrics, is adding to soil morphologic techniques by using multiple proximal sensing techniques such as pXRF, image acquisition and processing of soil profiles (Hartemink and Minasny, 2014).

Soil scientists describe soil profiles, vertical cross-sections of the soil representative of a three-dimensional pedon. A pedon is the smallest volume that is recognized as a soil, and it is best to determine field morphology of a soil profile using a recently opened pit (or a fresh road cutting) (Soil Science Division Staff, 2017). The soil scientist begins by organizing and subdividing the soil profile into reasonably distinct layers or pedogenic horizons. A soil description includes a site characterization and horizon depth intervals, horizon boundary characteristics, color, texture, structure, consistence, roots and pores, pH, effervescence, and special features of each horizon (Soil Science Division Staff, 2017).

Site characterization

The soil pedon features at a site result from the combined action of five soil-forming factors: parent material, biota, climate, topography, and time (Jenny, 1941). It is important to identify the parent material because some soil properties are inherited (Brewer, 1976). Knowledge of parent material combined with the observable features in the landscape conveys information about the formation and expected behavior of a soil. Descriptions need to be as precise as possible, including the geomorphic information, physiographic information, and surface morphometry. The physiographic information includes: (1) physiographic division, (2) physiographic province, (3) physiographic section, (4) state physiographic area, and (5) local physiographic or geographic name. The geomorphic information includes: (1) landscape, (2) landform, (3) microfeatures, and (4) anthropogenic features. The surface morphometry information includes: (1) elevation, (2) slope aspect, (3) slope gradient, (4) slope complexity, (5) slope shape, (6) geomorphic components, and (7) microrelief. The scientist describes the vegetation type, listing the common names of plants and their scientific names, when possible. Latitude and longitude, in degrees, seconds, and minutes, are most commonly used to record the geographical location of the soil as precisely as possible. Site characterization is organized as a hierarchy, typically starting with general setting of the site (physiography, landform, landform position, microfeatures, exposure, etc.) followed by a detailed description of the soil pedon or profile. The order may change depending on the local survey conditions. The hierarchical approach provides a better understanding of the observed pedon and horizon features and also connections with geographic, climatic, physiographic, and landscape settings (Schoeneberger et al., 2012).

Horizons

Soil horizons may be the most distinctive visual features of a soil profile. Both the *Soil Survey Manual* (Soil Science Division Staff, 2017) and World Reference Base for Soil Resources (IUSS Working Group WRB, 2015), refer to horizon(s) as a layer(s) approximately parallel to the surface of the soil, distinguishable from adjacent layers by a distinctive set of properties produced by the soil-forming processes. In the case of US Soil Taxonomy (Soil Survey Staff, 2010) the term 'layer,' rather than 'horizon,' is used if all the properties are believed to be inherited from the parent material. For example, recent loess or alluvial deposits that have not undergone in situ soil development or pedogenesis are considered soil layers. Horizons are typically described in two dimensions, vertically and horizontally.

The soil scientist first determines the horizon designation (label) and records the horizon thickness. Horizons are labeled according to diagnostic features (i.e., color, structure, texture, rock fragment content, etc.) and interpretations (i.e., how the horizon formed and how it responds to anthropogenic influence). The master horizon label represents characteristic properties. In the classification system developed by the U.S. Department of Agriculture (USDA) (Soil Survey Staff, 2010) capital letters (O, A, E, B, C, R, and V) indicate master horizons. Similar terminology for naming the main horizons is also used by the World Reference Base for

Soil Resources (IUSS Working Group WRB., 2015). As an example, the designations according to the U.S Soil Taxonomy (Soil Survey Staff, 2010) are as follows:

horizons and layers—Horizons or layers dominated by organic material. Some are saturated with water for long periods of time or were once saturated but are now artificially drained; others have never been saturated.

A horizons—Mineral horizons that formed at the surface or below an O horizon which exhibit obliteration of all or much of the original rock structure and that show one or more of the following: (1) an accumulation of humified organic matter intimately mixed with the mineral fraction and not dominated by properties characteristic of E or B horizons, or (2) properties resulting from cultivation, pastures, or similar kinds of disturbance.

E horizons—Mineral horizons in which the main feature is loss of silicate clay, iron, aluminum, or some combination of these, resulting in a concentration of sand and silt particles.

B horizons—Horizons that formed below an A, E, or O horizon, have soil structure, and show one or more of the following: (1) illuvial concentration of silicate clay, iron, aluminum, humus, carbonates, gypsum, or silica, alone or in combination; (2) evidence of the removal of carbonates; (3) residual concentration of sesquioxides; (4) coatings of sesquioxides that make the horizon color conspicuously lower in value, higher in chroma, or redder in hue than overlying and underlying horizons without apparent illuviation of iron; (5) alteration that forms granular, blocky, or prismatic structure if volume changes accompany changes in moisture content; or (6) brittleness.

C horizons or layers—Horizons or layers, excluding hard bedrock, that are little affected by pedogenic processes and lack properties of O, A, E, and B horizons. The material of C layers may be either like or unlike that from which the solum (horizons above the C) presumably formed.

R layers—Bedrock or strongly cemented to indurated. Examples are granite, basalt, quartzite, limestone, and sandstone. These layers are difficult to excavate and dig with handheld tools like spades but can be destroyed with heavy equipment.

V horizons—Mineral horizons that formed at the soil surface or below a layer of rock fragments (e.g., desert pavement), a physical or biological crust, or recently deposited eolian material.

Transitional and combination horizons

Horizons may result from two master horizons or layers transitioning into each other or contain portions of two distinct master horizons. Transitional soil horizons may be dominated by properties of one master horizon but have subordinate properties of another; for these horizons, symbols of master horizons may be combined (i.e., AB, EB, CB, BC, etc.). Combination horizons have materials that can be described separately regarding color, texture, and structure; a virgule (/) is used in their symbol to indicate the two source horizons (i.e., Bw/A, Bt/A, C/Bt, etc.).

Designations of master soil horizons are supplemented with suffixes or subscripts to convey more information about formation processes. Description systems vary slightly. Table 1 lists the suffixes used by the USDA (Soil Survey Staff, 2010). The World Reference Base for Soil Resources (IUSS Working Group WRB., 2015) uses similar qualifiers to describe different horizons and their associated pedogenetic processes.

Table 1 Suffix symbols used by the USDA for master horizons.

<i>Suffix</i>	<i>Horizon</i>
a	Highly decomposed organic material
b	Buried genetic horizon
c	Concretions or nodules
co	Coprogenous earth
d	Physical root restriction
di	Diatomaceous earth
e	Organic material of intermediate decomposition
f	Frozen soil or water
ff	Dry permafrost
g	Strong gleying
h	Illuvial accumulation of organic matter
i	Slightly decomposed organic material
j	Accumulation of jarosite
jj	Evidence of cryoturbation
k	Accumulation of carbonates
kk	Engulfment of horizon by secondary carbonates
m	Cementation or induration
ma	Marl
n	Accumulation of sodium

Types of soil horizons and layers were developed from soil formation and pedogenic concepts based on field investigations and laboratory analysis. Properties can vary greatly between soil types and horizons, with varying degrees of continuity that can be described as very abrupt, abrupt, clear, gradual, or diffuse (Soil Survey Staff, 2010). There are no hard rules in labeling horizons. Labeling is an interpretation based on observations by the scientist. The classification of the soil, however, is based on the description and measured soil properties and follows strict criteria.

Soil texture

Soil texture is one of the most common features used by scientists and laymen to describe soils. Texture refers to the relative abundance, by weight, of the size fractions—sand, silt, and clay. Particles less than or equal to 2 mm make up the ‘fine-earth fraction.’ This is one of the most important fractions for determining chemical, biological and some physical properties (Soil Survey Staff, 2014). In all textural classification systems, the sum of all these particles (by weight) equals 100% (Fig. 1). The several textural classification systems have varying ranges of particles sizes (Fig. 2).

Textural descriptions such as gritty, smooth, and sticky are commonly used because determining the percentage of sand, silt, and clay can be cumbersome. Commonly, field estimates of sand, silt, and clay are used, and the soils are placed into textural classes. These textures are verified by laboratory analysis. The mineralogy of the clay may affect estimates of clay in field textures. The kaolinitic clays expand little and tend to be harder to discern than smectitic clays by ‘feel texture,’ resulting in an underestimate of the clay percentage.

Soil texture relates to many of the ways a soil performs. If a soil is coarse (sandy), water tends to move through it without much impediment and the soil may not retain adequate amounts of water for plant growth. If a soil is clayey, water will probably move more slowly and be retained for plant growth; however, not all the water may be available or easily accessed by plant roots because clay can bond to the water. The shrink–swell potential of clayey soils varies depending on the type of clay minerals. If the soil is high in smectitic clay minerals, it will shrink and swell as the moisture content of the soil changes. This shrinking and swelling must be considered in the designs of infrastructures, such as roads and foundations. Clayey soils that primarily consist of kaolinite and other low-activity minerals have fewer limitations on designs. If more than 15%, by volume, of the soil consists of particles larger than 2 mm, prefixes or modifiers are added to the textural classes to indicate the amounts and type of fragments. These separates are classed as gravel, cobbles, stones, or boulders (Fig. 2).

Soil color

Soil colors can infer pedogenic processes in soils. The main pigmenting agents in soils are organic matter, iron, and, to a lesser extent, manganese and sulfur compounds; they cover the natural color of mineral grains (most of which are gray). Fig. 3 shows two

soils that have similar texture and structure yet differ in color. If a soil horizon has more than one color, the dominant color, by volume, is considered the matrix color.

Soil colors can be conveniently identified using a soil color chart. Soil scientists generally use Munsell color charts (Munsell Soil Color Charts, 1994). The charts arrange color by hue, value, and chroma. A combination of these three variables is used for all colors. Hue is the dominant spectral (rainbow) color; it is related to the dominant wavelength of the light. Value refers to the relative lightness of the color; it is a function (approximately the square root) of the total amount of light. Chroma is the relative purity or strength of the spectral color; it increases in value as grayness decreases.

Each soil color chart represents a specific hue, indicated in the upper right-hand corner (Fig. 4). The colors become successively lighter from bottom to top as the value increases. They increase in chroma to the right and become grayer to the left. The value and

Fig. 4 A Munsell soil color chart for hue 2.5YR, value 2.5–8, and chroma 1–8. Reproduced from Munsell Soil Color Charts (1994) Revised Edition, Macbeth Division of Kollmorgen Instruments Corporation, 405 Little Britain road, New Windsor, NY, 12553.

chroma of each color are shown beneath the color chip. As arranged in the chart, the colors form three scales: (1) radial, or from one card to the next, in hue; (2) vertical in value; and (3) horizontal in chroma (Fig. 5).

The matrix color (the dominant color) is the first color described in a soil horizon or layer. The moisture status (moist or dry) of the soil must be considered when describing soil color. When determining soil color, a soil scientist uses a fresh ped interior, to eliminate the possibility of describing the color of a ped surface coating (Fig. 6). While the Munsell color system continues to be widely used in the field, the use of spectral sensors has led to the use of other colors schemes like CIE (Commission Internationale de l'Eclairage—CIE | International Commission on Illumination/Comission internationale de l'Eclairage/Internationale Beleuchtungskommission), XYZ (Red, Green, Blue—RGB) color space (CIE, 1932). The CIE color space links the wavelength in the visible spectrum quantitatively with color visions (like Munsell color charts) perceived by humans. These links allow for quantitative analysis of soil colors in the visible range which is very useful in digital soil morphometrics (Hartemink and Minasny, 2014).

Redoximorphic features and mottles

A lack of uniformity in soil color can provide insight into the pedogenesis of the soil. In the USDA description terminology, the generic term 'mottle' was changed to 'redoximorphic feature' to describe soil features resulting from reduction and oxidation processes. The term 'redoximorphic feature' better describes the drainage status of the soil. The term 'mottles' does not infer a pedogenic process.

Redoximorphic features

Soil colors are greatly affected by the amount of oxygen in the soil. If there is sufficient oxygen for microbial activity, the soil is typically brown or red and frequently has a single dominant color. However, when the soil becomes wet (saturated with water), the

Fig. 5 A diagram showing relationships between hue, value, and chroma in the Munsell color system. Reproduced from <https://commons.wikimedia.org/wiki/File:Munsell-system.svg>. Shared according to Creative Commons Attribution ShareAlike 3.0 license (Accessed 26 January, 2022).

Fig. 6 A freshly broken ped with the exposed interior is held next to a Munsell soil color chart. Reproduced from John A. Kelley Collection, USDA Natural Resources Conservation Service (<https://www.flickr.com/photos/soilscience/albums>). oxygen supply cannot flow as freely and may become insufficient for many microbes. Insufficient oxygen in the soil causes reduction—a process by which iron and manganese gain electrons. Reducing conditions in soils are precursors to redoximorphic features (Vepraskas, 1992). Reduction of iron and manganese greatly increases their solubility, allowing them to dissolve into solution and move with the water (i.e., become mobile). Soil features caused by reduction and subsequent reoxidation are also redoximorphic features.

When the iron in the soil dissolves in solution, the coating is removed from the surface of the mineral grains, resulting in zones called 'depletions.' The color of depletions is that of the mineral grains, usually gray. When air reenters the soil, the iron and

Fig. 7 (a) Soil with redoximorphic features associated with iron (Fe) depletions (gray colors) and iron concentrations (reddish colors), in the matrix and along soil pores. (b) Soil with manganese (Mn) concentrations (black colors). Modified from John A. Kelley Collection, USDA Natural Resources Conservation Service (<https://www.flickr.com/photos/soilscience/albums>). Shared according to Creative Commons License terms (<https://creativecommons.org/licenses/by/2.0/>).

manganese are oxidized and precipitate into brownish, reddish, or blackish forms called ‘concentrations.’ Thus, depletions are caused by removal of iron coatings, and concentrations are caused by oxidation and precipitation of previously reduced forms of iron and manganese. Both depletions and concentrations require reduction, but only concentrations require subsequent reoxidation.

Concentrations and depletions are described by kind, size, abundance, and color (Schoeneberger et al., 2012). Concentrations are usually browner, redder, or blacker than the matrix (Fig. 7). There are several kinds of concentrations, including finely disseminated materials, masses (non-cemented), nodules, and concretions (cemented). Concretions and nodules are both cemented accumulations of iron and manganese but differ in their internal structure: concretions have concentric rings whereas nodules do not (Fig. 7). Depletions are usually lighter colored than the matrix (Fig. 3, Coxville soil). There are two types of depletions: (1) iron depletions, which are primarily a lighter color than the matrix; and (2) clay depletions, which have the light gray color but also have lost clay and thus are grainier.

Mottles

Mottles are areas that have a different color from the matrix. They commonly have lithochromic or lithomorph colors. These features typically are inherited from the geologic parent material rather than the result of pedogenesis. Relict redoximorphic features associated with mottles are features that formed in a pluvial environment or in landscape that has been naturally or anthropogenically altered and permanently affects the drainage of the soil (Fig. 8). Description of mottles may include abundance, size, contrast (to matrix), color, and name.

Soil structure

Soil structure refers to units composed of primary particles. The cohesion within the units is greater than the adhesion among them. Soil structure results from processes that aggregate, cement, compact, or unconsolidated soil particles. Under stress, the soil mass tends to rupture along predetermined planes or zones. The peds form repetitive, quasi-uniform shapes varying in size from millimeters to centimeters and result from the aggregation of soil particles held together by the electrical charges on the surfaces of the minerals and organic matter (Fig. 9). An undisturbed soil has several levels of structure, which can be divided into primary, secondary (compound), and tertiary. Morphological descriptions identify the primary structure. Soil structure can be defined by: (1) the size, shape, and arrangement of peds, (2) the voids between peds, and (3) the associated interpedal pedological features in a soil material.

Clods and fragments differ from peds. Peds are a result of soil-forming processes, whereas clods and fragments are not. Clods result from a disturbance, such as plowing or digging that molds the soil to a transient mass which slakes with repeated wetting and drying. Fragments include: (1) units of undisturbed soil with bounding planes of weakness that are formed on drying without application of external force and which do not appear to have predetermined bounding planes; (2) units of soil disturbed by

mechanical means but without significant rearrangement to a denser configuration; and (3) pieces of soil bounded by planes of weakness caused by pressure exerted during examination, with size and shape highly dependent on the manner of manipulation.

Some soils lack structure and are referred to as structureless. When structureless soils are ruptured, soil fragments, single grains, or both may result. Structureless soil may be either 'massive' or 'single grain.' Massive soils tend to form fragments when disturbed, and single grain soils are typically sandy and loose in 50% or more of the volume (Fig. 10).

Shape

Several basic shapes are recognized for soil structural units. Supplemental statements about variations in shape of individual peds are needed in detailed descriptions of some soils. Table 2 and Fig. 11 identify the possible shapes of soil structure.

Size

Five classes are used to describe the size of structural units: very fine, fine, medium, coarse, and very coarse. The size limits vary according to the shape of the unit. They refer to the smallest dimension of plates, prisms, and columns.

Table 2 Types of soil structure.

Structure	Description
<i>Natural soil structural units (pedogenic structure)</i>	
Granular	Small peds with rounded or very irregular faces
Angular blocky	Peds with faces that intersect at sharp angles
Subangular blocky	Peds with sub-rounded shapes and no sharp angles
Platy	Flat, plate-shaped units
Wedge	Elliptical, interlocking lenses that terminate in acute angles and are bounded by slickensides
Prismatic	Vertically elongated peds with flat tops
Columnar	Vertically elongated peds with rounded tops
<i>Structureless</i>	
Single grain	Absence of structural units; entirely noncoherent material; e.g., loose sand
Massive	Absence of structural units; coherent mass of material

Grade

The distinctness of soil structural units is described by grades based on the relationship between cohesion within units to adhesion between units (i.e., the ease with which the units separate and the proportion of units that hold together when the soil is handled). There are three grade classes:

Weak—Units are barely observable in situ. When gently disturbed, the soil material parts into a mixture of whole and broken units and mainly exhibits no planes of weakness. Faces that indicate persistence through wet-dry cycles are evident.

Moderate—Units are well formed and evident in undisturbed soil. When disturbed, the soil material parts into a mixture of mostly whole units, some broken units, and material that is not units. Peds part from adjoining peds to reveal nearly entire faces that have properties distinct from those of fractured surfaces.

Strong—Units are distinct in undisturbed soil. They separate cleanly when the soil is disturbed. When removed, the soil material separates mainly into whole units.

The degree of disturbance required to determine structure grade depends largely on moisture content and percentage and mineralogy of clay. Slight disturbance only may be necessary to separate the units of moist sandy loam with strong granular structure, while considerable disturbance may be required to separate units of moist clay loam with strong blocky structure.

The designation of structure grade, size, and shape can be modified with other appropriate terms when necessary to describe other characteristics. Surface characteristics of units are described separately. Special structural units, such as wedge-shaped units of soils with a high shrink-swell potential, are described if present.

Compound structure

‘Compound structure,’ another term for ‘secondary structure,’ refers to smaller structural units that are held together to form larger units. Grade, size, and shape can be described for both sets of units as well as the relationship of one set to the other. Examples of compound structure are ‘strong medium blocks within moderate coarse prisms’ and ‘moderate coarse prismatic structure parting to strong medium blocky.’

Soil consistence

Consistence refers to the cohesion and adhesion within a soil or its resistance to deformation or rupture. Soil consistence largely depends on soil moisture. It can be expressed as rupture resistance, surface crust formation, manner of failure, stickiness, plasticity, and penetration resistance.

Consistence is typically described by field evaluation (i.e., rupture resistance). A soil sample 25–30 mm long is held between the thumb and first finger and pressure is applied. The moisture content of the sample is an important part of the calculation.

Soils in humid and subhumid climates may form brittle subsurface horizons. The degree and percentage of brittleness of the soil are described. Soils may also be hardened due to cementation. The accumulated materials, such as carbonates, gypsum, humus, iron, and or silica, are listed. In addition, the percentage of cementation and its strength are noted.

Roots and pores

Soils are penetrated by roots that grow underneath the surface that anchor plants while absorbing water and nutrient from the soil. The larger soil roots and pores can be observed in the field (Fig. 12). The larger pores (macropores?) are mostly noncapillary pores, i.e., pores that cannot hold water against the force of gravity. They are important for the movement of water and air within the soil. After a major wet event (rainfall, snowmelt, irrigation, etc.), these pores transmit the water throughout the soil to the smaller capillary pores. The noncapillary pores redistribute the water in a few days; as they drain, oxygen (air) is distributed into the soil. If soil oxygen is depleted for more than a few days, many plants will die or be harmed.

Soils with a mixture of noncapillary and capillary pores are best suited to plant growth because they both drain well and retain water. The roots and pores are described based on abundance and size classes (for example, common fine roots, many medium pores, etc.).

Chemical response

pH

Much information can be inferred from the acidity or alkalinity of a soil. Soil pH can be estimated with a simple field test kit. Each horizon or layer within a pedon is tested because pH may vary significantly due to pedogenic or lithogenic properties. There are several soil pH class systems that categorize soil pH.

Fig. 12 A soil with root distribution showing small pores (enlarged inset) and clay films. Modified from John A. Kelley Collection, USDA Natural Resources Conservation Service (<https://www.flickr.com/photos/soilscience/albums>). Shared according to Creative Commons License terms (<https://creativecommons.org/licenses/by/2.0/>).

Effervescence

A simple field technique may be used to check for the presence of free carbonates. A 10% solution of HCl added to the soil produces a gaseous response when CaCO_3 (calcium carbonate) is present. The gaseous response will vary depending on the amount of carbonates in the soil. The degree of effervescence is noted in the description.

Reaction to alpha,alpha'-dipyridyl

In soils that are actively reducing at an Eh (redox potential) or pE (relative electron activity) low enough to produce ferrous iron, a 0.2% concentration of alpha,alpha'-dipyridyl (also listed as 2,2'-bipyridine) may be used (U.S. Department of Agriculture, Natural Resources Conservation Service, 2022; Childs, 1981). This solution is applied to the soil within minutes of exposure to air but in the absence of sunlight. If Fe^{2+} (ferrous iron) is present, the alpha,alpha'-dipyridyl will become red or pink; if only Fe^{3+} (ferric iron) is present, the solution will remain clear (Fig. 13).

Because this solution will react with just a few parts per million of Fe^{2+} , care is needed when extracting the soil. Ferrous iron can be transferred from a knife blade or spade and produce a false-positive response. The solution should only be used when reducing conditions are suspected.

Fig. 13 A soil sample before (a) and after (b) being treated with alpha,alpha'-dipyridyl. Ferrous iron is detected (reddish areas in right image). Reproduced from John A. Special features

Pedon features

Pedon features occur throughout soils and may cross adjacent horizons (Fig. 14). These features are described using standard technical terms. In some cases, additional information is needed in the description (Table 3).

Ped surface features

Surface features form from a variety of pedogenic processes. They differ from the matrix soil in composition, orientation, or packing. These features include: (1) coats of a variety of substances unlike the adjacent soil material that cover part or all of surfaces; (2) material concentrated on surfaces by the removal of other material; and (3) stress formations in which thin layers at the surface have undergone reorientation or packing by stress or shear. Descriptions of surface features may include kind, location, amount, continuity, distinctness, and thickness. Table 4 lists common ped surface features. Selected examples are shown in Fig. 15.

Table 3 Common pedon features.

<i>Pedon feature</i>	<i>Description</i>
Cracks	Fissures other than those attributed to soil structure
Desert pavement	Natural concentration of polished gravel and stones at the soil surface, primarily in arid and semiarid climates
Ice crystals, lenses, layers (veins), wedges	Features occurring in soils of Arctic, Antarctic, and Subarctic regions
Jarosite mottles	Yellow jarosite mineral accumulations resulting from oxidation of sulfidic accumulations
Krotovinas	Irregular tubular streaks of soil material transported from one horizon or layer to another by biologic activity
Lamellae	Thin banded illuviated clay
Microbiotic crust	Thin surficial zone exhibiting more mechanical continuity of the soil fabric than the subjacent soil
Stone line	Natural accumulation of coarse fragments below the surface that extends horizontally through the pedon
Tongues of albic material	Lobes of eluviated soil that extend into a soil horizon from overlying horizons

Reproduced from Schoeneberger PJ, Wysocki DA, Benham EC, and Soil Survey Staff (2012) *Field Book for Describing and Sampling Soils, Version 3.0*. USDA Natural Resources Conservation Service, National Soil Survey.

Table 4 Common ped surface features.

<i>Ped feature</i>	<i>Description</i>
Clay films	Layers of oriented, translocated clay (clay skins)
Clay bridges	Links between mineral grains occurring primarily in sandy soils
Stress surfaces, pressure faces	Smooth, shiny, or smeared surfaces formed through rearrangement of particles due to shear forces
Slickensides	Stress surfaces that are polished and striated; direction of movement can be determined from striations
Other features	Coats of iron, aluminum, or manganese oxides, organic matter, salts, or carbonates

Reproduced from Schoeneberger PJ, Wysocki DA, Benham EC, and Soil Survey Staff (2012) *Field Book for Describing and Sampling Soils, Version 3.0*. USDA Natural Resources Conservation Service, National Soil Survey.

In: Ditzler C, Scheffe K, and Monger HC (eds) *USDA Handbook 18*. Washington, DC: Government Printing Office.

Location

Surface features may vary in the coverage of peds or may coat other soil constituents such as gravel or rocks.

Amount

The number of ped surface features is noted as a percentage or a percentage range. If a horizon has more than one surface feature, each surface feature is noted with the percentages of that feature.

Horizon or layer features

Boundary

Soil horizons or layers generally are oriented parallel to the surface. In some soils, however, they are oriented differently because of pedogenesis. In most description systems, the bottom boundary of the soil horizon or layer is described as smooth, wavy, irregular, or broken (Fig. 16). The distance over which the boundary grades into another horizon or changes is also usually described. Boundaries can be identified by classes: abrupt (0–2 cm), clear (2–5 cm), gradual (5–15 cm), and diffuse (more than 15 cm).

(a)

(b) A mid-infrared (MIR) instrument for determining soil properties based on soil reflectance (personal contribution).

Proximal sensing

Field observations and measurements, whether based on human sensors (sight, touch, etc.) or chemical sensors (acid and alkaline solutions, etc.), can be time-consuming or costly, or both. Proximal soil sensing is a faster and often cheaper technology (Viscarra Rossel et al., 2011). It uses sensors close to, or in direct contact with, the soil surface and measures soil properties directly or indirectly. Two methods used to document soil properties at specific locations (point data) are portable X-ray fluorescence (P-XRF) and optical reflectance (Fig. 17).

Portable X-ray fluorescence (P-XRF) uses high-energy X-ray photons to destabilize electrons, which emit X-ray energy when moving from outer to inner orbits (shell). Because different chemical elements emit specific fluorescence, they can be identified and quantified. The p-XRF has many applications, including (i) to differentiate soil horizons based on the concentration of different metals; (ii) to quantify the calcium content and percent of gypsum; (iii) to assess differences in weathering indices, mineralogy, and geologic signatures related to soil development; and (iv) to characterize differences in mineralogy and lithology.

Optical reflectance is based on the soil's ability to reflect light in different parts of the electromagnetic spectrum. The spectrum includes ultraviolet (100–400 nm), visible (400–750 nm), near infrared (750–2500 nm), and mid-infrared (2500–25,000 nm) wavelengths. Measurements obtained using optical sensors can be related to many soil properties, such as soil mineral composition, texture (sand, silt, and clay content), soil color, moisture, organic carbon content, pH, cation-exchange capacity, and carbonates.

Digital soil profile description (digital soil morphometrics)

Digital soil morphometrics is based on proximal sensing tools and techniques to measure and quantify soil properties and could complement existing description and analytical methods. In addition, it may offer new insights in soil horizon development and classification (Hartemink and Minasny, 2014). One of the main expected benefits of digital soil morphometrics is the quantification of soil profile descriptions to create continuous soil depth functions that can be related to other laboratory measured soil properties. Digital soil morphometrics can be used for soil horizons, colors, texture, structure, coarse fragments, pores, and roots, etc., (Gallegos et al., 2021). Analysis of the observations and images from the soil profile use image analysis and pattern recognition software and multiple steps for processing (Figs. 18–20).

Soil micromorphological description

Most of this chapter has focused on the macromorphological description of soils in the field, but micromorphological descriptions can be made by laboratory analysis of soil thin sections (Bullock et al., 1985). Micromorphological descriptions can supplement and verify soil features and are valuable for classifying soils and understanding pedogenesis. Fig. 21 illustrates the use of thin sections to quantify pore size, shape, and distribution, information important in understanding water movement through the soil profile (Libohova et al., 2015).

Conclusions

Traditionally, soil morphology has provided the first clues about soils, properties and pedogenesis under field conditions as observed by soil scientists using simple tools like a knife, tape measure, water bottle, Munsell color book, 10× hand lens, 10% HCl

(hydrochloric acid), a clinometer etc. Soil micromorphology added polarizing light microscopes and thin sections among other tools for describing and quantifying soil features such as pore size and distribution, mineralogy, etc. The development of proximal sensors such as portable X-ray fluorescence (pXRF), mid-infrared spectroscopy (MIR), etc., has taken soil morphology and micromorphology all together to the new era of digital soil morphometrics. The continuous development of new tools and sensors for observing soils, on one hand, brings the soil morphology and micromorphology closer to biological, physical, and chemical soil analysis. On the other hand, digital soil morphometrics promises quantitative analysis and evaluations of complex soil systems through a combination of the relevant tools and sensors with powerful software and machine learning algorithms.

Abstract

Soil micromorphology is the technique in soil science that enables us to observe how soil constituents are organized at a microscopic scale, i.e., between field and submicroscopic observations. Special terms are used to study and describe soil microfabrics viewed in soil thin sections, which have evolved from a genetic to a more morphoanalytical approach. The applications of soil micromorphology extend to most fields of the earth and archaeological sciences, but it is in soil genesis, paleopedology and geoarchaeology where it has been most useful to determine relative chronologies of processes.

Key points

- In the continuum of soil observation, soil micromorphology fills the gap between field and submicroscopic scales.
- Special concepts and terms are needed to describe and understand the organization of soil constituents at the microscopic scale.
- The interpretation of micromorphological features needs to establish relationships between features and processes that lead to them.
- Soil micromorphology has been applied to soil genesis, soil management, soil classification, geomorphology, paleopedology, archaeology and forensic sciences among other disciplines within earth sciences.

*Deceased.

Introduction

Soil micromorphology is the observation and interpretation of undisturbed, oriented samples of soil material by microscopic and ultramicroscopic techniques to identify their constituents (including voids) and to determine their mutual relations in space and time. In the continuum of observation of soil cover: pedological systems—horizons—materials—elementary organizations (FAO/ISRIC/ISSS, 1998), soil micromorphology deals with the latter two levels. They require special techniques to observe and study them. Soil micromorphology allows us to deduce genetic and chronological relationships between constituents; this is soil genesis in its widest sense, comprising natural and also human induced processes, e.g., by drainage, irrigation or management. Other techniques, such as in soil chemistry, physics and mineralogy often deal with homogenized bulked samples where heterogeneity and anisotropy are lost, whereas micromorphology enables us to observe and measure the micro-heterogeneity and anisotropy in undisturbed samples. For example, chemistry provides results on the total content of calcium carbonate, whereas micromorphology distinguishes between lithogenic or pedogenic calcite or aragonite present as coatings or nodules.

At the outset the term ‘micropedology’ was commonly used, which seemed to narrow the approach to pedogenetic studies only. It was soon replaced by ‘soil micromorphology,’ to emphasize its broader use.

To keep the samples undisturbed, special sampling techniques have been developed. Most micromorphological studies are made with a petrographic microscope, using polarized light with thin sections prepared from resin impregnated blocks, sometimes completed by ultramicroscopic techniques and/or microanalyses.

In the second half of the 20th century soil micromorphology was mainly used as a tool for pedogenic research and to support the development of soil classifications. When funds for these disciplines decreased, and therefore the use of micromorphology by soil scientists, this was compensated for by an increase in interest by palaeopedologists, Quaternary geologists and especially geoarchaeologists.

History

Soil thin section analyses were recognized as a valuable technique in soil science after the publication of Kubiěna’s book “Micropedology” in 1938. It introduced concepts and terms to distinguish between coarse constituents (‘fabric skeleton’) and fine constituents and their state (‘fabric plasma,’ peptized or pectized) and their configurational relationship (‘elementary fabrics’). In his later publications Kubiěna (1938) no longer considered individual constituents, but the overall aspect of the thin section, naming it after the soil type in which it characteristically occurred, such as Braunlehm, Braunerde or Rotlehm. This system was in use until the end of the 1960s for soils in Europe, North America and partly for humid tropical soils.

The interpretation of soil thin sections was then mainly limited to a mention of the corresponding soil-type described by Kubiěna (Braunlehm, Rotlehm, etc.), thus as a basis for classification only. This implied that the pedogenesis of these materials described by Kubiěna was also accepted, although his interpretation was not based on other evidence such as chemical, physical or mineralogical analyses. Therefore, its use was applied more to European soils, than to the as yet not well understood soils of the tropics.

Early in the 1960s the technology for thin section preparation considerably improved with the use of cold-setting polystyrene for impregnation, which avoided the artefacts often observed in the thin sections of soils made with resins that needed heating, as done before. Moreover, it enabled the preparation of larger samples (e.g., thin sections of 90 mm × 180 mm, compared to 28 mm × 48 mm previously) and the analysis of larger fabrics and structures.

The Australian geologist Roy Brewer published several papers, starting from 1960, on a new analytical approach to micromorphology, which were compiled in 1964 in his famous book ‘Fabric and Mineral Analysis of Soils’. He was the first scientist to make a clear distinction between the undifferentiated groundmass (called ‘s-matrix’), composed of immobile coarse constituents (the ‘skeleton grains’) and the mobile, fine mass (‘plasma’), and the organized special pedogenic features (‘pedological features’). Pores (voids) were treated as equally important fabric constituents. A weak point was that organic material was totally ignored. This system soon became used worldwide in the second half of the 1960s. However, as many new soils were discovered and studied in the arid and humid tropics, it became clear that the system was incomplete and contained contradictions. This resulted in additions by several authors, and also in an uncontrolled proliferation of terms.

In this approach the individual constituents and features were identified, which made it possible to quantify them. In the first part of the 1960s this was done by manual point counting, as used in petrography, but later in that decade the first tools for image analysis became available, and were mainly used for porosity studies. The first scanning electron microscopes and microprobes also became commercially available in that period for in situ study of fabrics and constituents at high magnification.

To come to a coherent, internationally accepted morphoanalytical system, a working group was created by the ISSS (now IUSS) in 1969. This resulted in the publication of a handbook by Bullock et al. (1985) with precisely defined concepts and terms that were partly based on Brewer’s system, but with important contributions of sedimentary petrography and botany. The system was applied worldwide as a standard for soil thin section analysis. When the book was out of print at the end of the 1990s, the Soil Science Society of America asked Georges Stoops to prepare a revised and updated version (Stoops, 2003), which contained keys for the morphometric identification of several features. After this was out of print at the end of the 2010, an updated version was prepared (Stoops, 2021).

In the former Soviet Union terms borrowed from traditional Russian sedimentary petrography, completed with terms from Kubiěna, were still used for some time, but were gradually replaced by the system of Bullock et al. (1985) and Stoops (2003).

Much effort was made to synthesize systems for thin section descriptions, but this was not the case for interpretation. Apart from the books by FitzPatrick (1984, 1993) based on his own experience, and rare review papers on specific soil types, scientists had to rely on papers in journals and proceedings that dealt with local soils. Until 1965 fewer than 40% of the papers were published in English (Stoops, 2014). The first overall review paper on natural soils was published only 10 years ago (Stoops et al., 2010, 2018), whereas for archaeological materials the following books became available: Courty et al. (1989), Nicosia and Stoops (2017) and Macphail and Goldberg (2018).

For more information and references of the publications cited in this entry, the reader is referred to Stoops (2009).

Techniques

Sampling and thin section preparation

By definition, soil micromorphology concerns the study of undisturbed samples, therefore, special sampling techniques are necessary. During the whole process from sampling in the field through to the different sample treatments, it is essential to keep the soil constituents and microstructure as they were originally, and in such a way that they can be clearly observed by microscopic techniques. Therefore, any change in structure (crushing, swelling/shrinking, collapse) or composition (dissolution, mineralogical changes) should be avoided, as well as introducing any component that may interfere with the observation.

In the case of materials with enough coherence, blocks can be carved out of the profile and carefully packed with newspaper or plastic wrap, ensuring that the top and bottom orientations are clearly indicated. For less stable and loose soil materials the so called Kubiěna boxes were developed. These are metal boxes consisting of a frame that can be opened, and with two covers (top and bottom). The frame is gently inserted into the profile wall by pressing on a pre-carved block. After removal the box is closed with the two covers, and the sample number and orientation are marked on the frame. As cheaper alternatives recycled cardboard boxes (tetra-brick type) or special plastic boxes are sometimes used. Pre-carved blocks can be stabilized by enveloping them in plaster bandages or by spreading plaster of Paris inside the box before encasing the soil block, to give cohesion to it before its removal. The blocks are then stored in boxes after hardening. For more detail on sampling techniques and strategies see Nicosia and Stoops (2017), ch. 35.

Most soil micromorphology research is done on soil thin sections, although some can be done on polished block faces, whole blocks or on soil aggregates. To prepare a thin section, a hard material is needed. This can be obtained by impregnating the undisturbed soil sample, once removed from the box, under vacuum conditions with a cold-setting resin, mostly a diluted polystyrene. As the resin is incompatible with water, the latter has to be removed, either by air or oven drying, or by acetone replacement. This is done by submerging the sample in an acetone-water bath, and replacing the diluted acetone daily by a dilution progressively richer in acetone, until all water is extracted (about 1 week), or by putting the wet sample on a plate over a disk with acetone in a closed desiccator. An equilibrium will be established between water vapor and acetone vapor in the atmosphere. By replacing daily the acetone diluted by the water of the sample until it becomes pure acetone, all water will be gradually extracted (duration about 1 month). This procedure has the advantage that disturbance by shrinking, as a result of drying, is avoided.

After hardening, a slice of the impregnated block is cut with a diamond saw cooled with a special oil (to avoid solution of constituents by water). The slice is then ground and mounted on a support glass of corresponding sizes (e.g., 48 mm × 28 mm for a petrographic size thin section, up to 180 mm × 120 mm for a so called 'mammoth' thin section). By further sawing and grinding the thickness of the slice is reduced to 20–30 µm, the standard thickness of a thin section. At that thickness, most minerals are transparent, and can be determined by optical techniques. For grinding, a slurry of fine corundum or diamond powder and oil is used. Thin sections are sometimes covered with a very thin cover-glass for protection, unless staining tests, cathodoluminescence or microprobe studies are planned. For more detail and references see Murphy (1986).

Some differences to the basic procedure include, for example, percolation tests with dyeing agents as a pre-treatment to identify connected porosity, or the addition of fluorescent dyes to the resin so that porosity images can be obtained with UV (ultraviolet) light.

Observation techniques

The most common observation technique is optical microscopy, using a polarizing microscope (petrographic microscope). This requires at least a basic knowledge of optical crystallography (Stoops, 2021).

For specific research a range of additional techniques is available. The use of oblique incident light is needed to distinguish between opaque constituents and to determine their internal fabric. Incident UV or blue light can be used to detect specific minerals such as phosphates (e.g., bone splitters) and cellulose. When a fluorochrome (a photoreactive chemical) is added to the impregnating resin, observation in UV or blue light shows a clear image of the porosity. For cathodoluminescence studies an uncovered thin section is mounted in a small vacuum chamber with two glass windows and an electron gun is mounted on the stage. As the cathodoluminescence of some minerals, such as calcite, depends upon the presence of trace elements in the lattice, information on the different origins or pedogenic stages can be obtained (for more information see Nicosia and Stoops, 2017, ch 36).

Uncovered thin sections can also be treated with selective staining solutions (e.g., to distinguish between carbonates) or can be subjected to selective extraction treatments (e.g., for amorphous, organic bound or free iron oxides) (Stoops, 2021).

Since the 1970s, ultramicroscopic techniques, such as TEM (Transmission Electron Microscopy) on ultrathin slices or SEM (Scanning Electron Microscopy) on fracture surfaces, are used as complementary techniques. Microprobe studies of carbon coated uncovered thin sections are used to determine and map the chemical composition of constituents; μ -XRD (micro X Ray Diffraction) and μ -FTIR (micro Fourier Transform Infrared Spectroscopy) are other accessory techniques used on thin sections (Nicosia and Stoops, 2017).

Scans of the total thin section are also useful to observe soil structure and bioturbation by macrofauna. Photographic polarizing films can be used as polarizer and analyzer when scanning thin sections.

The X-ray computed tomography permits the visualization and quantification of soil porosity through the three-dimensional analysis of intact soil cores. Micron-scale X-ray CT (μ CT) is the preferred method to analyze intact soil blocks, which enables analysis of their structure, while allowing other tests on the same sample afterwards. Samples for this method do not need to be dried before analyses (Taina et al., 2008).

Study of thin sections

At present soil thin sections are generally analyzed and described according to internationally accepted concepts and terms proposed by Bullock et al. (1985) and later by Stoops (2003, 2021); these are summarized below. The terminology is available in 19 languages on <https://www.isric.org/explore/ISRIC-collections/micromulti> (accessed January 2022).

Analysis of the soil fabric comprises the description of the shape, relative size and frequency of the soil constituents and their spatial arrangement. The latter includes their orientation and distribution patterns.

Microstructure and groundmass

Microstructure deals with the size, shape and arrangement of primary particles (e.g., sand grains) or aggregates, and voids. Voids can include 'packing voids' (e.g., between grains of sand or between aggregates), 'planes' (e.g., between blocky peds), 'channels', 'chambers' (equidimensional voids interconnected by channels), 'vesicles' (spherical voids), 'vughs' (irregular equidimensional voids) and 'mouldic' voids (resulting from total dissolution of a constituent). Various types of 'peds' are considered: (sub)angular blocky, platy, lenticular, crumb and granular. Massive horizons often have a channel, vuggy or vesicular microstructure.

A distinction is made between the groundmass, composed of coarse and fine constituents and associated packing voids, and pedofeatures, discrete fabric units distinguishable from the adjacent groundmass by a difference in concentration of one or more constituents (e.g., clay coatings, iron nodules, gypsum crystals) or by a difference in fabric (e.g., a crescent arrangement due to biological activity). Three basic constituents are distinguished: coarse and fine material (either mineral or organic), and voids. The size limit between coarse and fine ('c/f limit') is not fixed and is a function of the type of material studied and the magnification used, but it is mainly between 2 μ m and 10 μ m. The coarse fraction comprises mineral grains (e.g., quartz, feldspar, mica), rock fragments (e.g., basalt, volcanic glass, sandstone), inorganic residues of biological origin (e.g., phytoliths, diatoms, shells, bones), anthropogenic elements (e.g., brick fragments, furnace slag) and larger organic remains. Their size, shape and abundance and degree of alteration need to be mentioned. The fine fraction contains, depending upon the c/f limit chosen, clay (e.g., clay minerals, short range order minerals, cryptocrystalline goethite or hematite, fine organic material) and fine silt particles, including microcrystalline calcite.

Organic material is important in horizons such as A1 and Bh. Depending upon the size and complexity one can recognize organ, tissue and cell residues, in addition to fine organic material such as opaque punctuations and amorphous material. In addition, the degree of decomposition is determined based on color, birefringence and sometimes fluorescence.

The way that the coarse and fine constituents are arranged is determined by their c/f (coarse/fine) related distribution pattern. Seven types are distinguished (Fig. 1): 'coarse monic': only coarser particles are present, 'chitonic': the fine particles occur as a coating around the larger ones, 'gefuric': the finer particles form bridges between the coarser, 'enaulic': the finer particles occur as aggregates between the coarser, 'porphyric': the coarser particles are embedded in a finer mass, and 'fine monic': only finer particles are present. Intergrades between these types commonly occur. Different types of microstructures and c/f related distribution patterns are shown in Fig. 2.

The fabric within the micromass cannot be observed directly because the constituent particles are below the resolution of the optical system. However, clay particles in soil form packages called 'domains' of parallel oriented flakes, which behave optically as single crystals, and therefore visible between crossed polars. Their arrangement enables identification of the birefringence fabric or b-fabric of the micromass. The following types of b-fabric are recognized: (i) 'undifferentiated': no interference colors visible between crossed polars (e.g., in allophanic or ferralitic materials); (ii) 'speckled': small equant domains occur (e.g., in most A1 horizons); (iii) 'striated': elongated domains (striae) that can occur on pore walls ('porostriated,' e.g., on slickensides), on grain boundaries ('granostriated'), as single streaks ('monostriated'), as parallel lines (parallel striated), as intersecting lines ('cross striated'), as rings ('circular striated'), as concentric rings ('concentric striated'), as bowlike features ('crescent striated') and without any specific pattern ('random striated'); (iv) 'crystallitic': the interference colors are caused by very small crystals, mostly of calcite, for example in arid soils. Striated fabric generally indicates the presence of swelling clay minerals, e.g., in Vertisols.

Fig. 1 Coarse/fine (c/f) related distributions: (1a) coarse monic; (1b) fine monic; (1c) chitonic with clay coatings (as in Bt); (1d) chitonic with organic coatings (as in spodic B); (1e) concave gefuric; (1f) convex gefuric; (1d) fine enaulic (aggregates smaller than coarse grains); (1e) equal enaulic (aggregates same size as coarse grains); (1f) close porphyric (grains are touching, although not always in the plane of the section); (1g) single spaced porphyric; (1h) double spaced porphyric; (1i) open porphyric. Pedofeatures: (2a) typical coating of iron-rich clay; (2b) hypocoating of iron-oxides; (2c) iron-oxide quasiccoating; (2d) organic rich capping on coarser grains; (2e) calcite pendants below coarser grains; (2f) loose continuous infilling; (2g) loose discontinuous infilling; (2h) dense complete infilling; (2i) dense incomplete infilling; (3a) lenticular gypsum crystals (left) and cubic pyrite crystals (right); (3b) crystal aggregate of gypsum; (3c) intrusive typical iron rich nodule; (3d) impregnative iron rich nodule; (3e) intrusive concentric nodule; (3f) impregnative concentric nodule; (3g) nucleic nodule; (3h) geodic calcite nodule; (3i) iron rich aggregate nodule; (3j) calcitic septaric nodule; (3k) different shapes of excrements; (3l) iron rich clayey intercalation.

Note the presence, inside some needles, of small, orange homogeneous ellipsoidal excrements. Litter layer under dune forest, Belgian coast.

Pedofeatures

Pedofeatures are subdivided according to their morphology, either related to surfaces or voids, or unrelated. The first group (Fig. 2) comprises 'coatings' and 'infillings' and the second includes (Fig. 3) 'nodules,' 'crystals' and 'crystal intergrowths,' 'intercallations' and 'excrements.' A second criterion distinguishes between 'matrix pedofeatures,' visible as an overprint over the groundmass (e.g., diffuse iron oxide impregnations, spots of calcite depletion) and 'intrusive pedofeatures' having no characteristics of the groundmass.

Fig. 3 Coatings and infillings. (A) Illuvial coating of coarse clay in channel, soil on calcareous fine colluvium, Catalonia. PPL (parallel polars). (B) Same in XPL (crossed polars). Note weak continuous orientation of clay in coating, and calcitic crystallitic b-fabric in the groundmass. (C) Complete dense infilling by fine, limpid illuvial clay with crescent pattern. Bt horizon on reworked till from weathered granite, Pyrenees. PPL. (D) Same, XPL. Note interference colors due to parallel orientation of the fine clay particles, and extinction lines parallel to polarizer and analyzer. (E) Multi-layered calcite pendent below a limestone fragment. Bk horizon in a doline, Mallorca. PPL. (F) Same in XPL. Note calcitic crystallitic b-fabric in groundmass. (G) Iron oxide pan resulting from the impregnation of the groundmass with reddish brown iron compounds. Bir horizon, Ireland. (H) Iron oxide hypoc coating on planar void in young volcanic ash deposit, Indonesia. Note presence of several parallel planar voids.

The features related to surfaces are subdivided into three groups: (i) 'coatings': intrusive pedofeatures occurring on the surface outside the groundmass (e.g., clay, calcite or goethite coatings); (ii) 'hypocoatings': matrix pedofeatures occurring directly on a surface, but inside the groundmass (e.g., microcrystalline calcite surrounding a root channel, iron depletion on a ped surface); (iii) 'quasicoatings': matrix pedofeatures related to a surface, but occurring at some distance from it (compare with Liesegang rings). According to their morphology, several types can be distinguished, e.g., typic, cappings (covering a larger constituent), pendants (underneath a larger constituent), crusts, pans. 'Infillings' are intrusive pedofeatures in void spaces. They are subdivided into 'loose continuous,' 'loose discontinuous' (e.g., excrements), 'dense complete' (e.g., illuvial clay) and 'dense incomplete' (e.g., calcite crystallization). Fig. 3 illustrates several types of infillings and coatings.

Pedofeatures not related to surfaces or voids can be subdivided in three groups (i) 'crystals and crystal intergrowths': these are euhedral or subhedral pedogenic crystals in the groundmass (e.g., lenticular gypsum in desert roses, cubic pyrite, vivianite); (ii) 'nodules': discrete bodies that can be intrusive or matrix features that can be either sharp or diffuse; they are subdivided according their internal fabric into 'typic' (undifferentiated), 'concentric,' 'nucleic' (with central core), 'geodic' (with a central void), 'septaric' (with concentric and radial cracks), 'aggregate' and 'dendritic' (composed of smaller nodules) and 'alteromorphic' (displaying the fabric of a weathered mineral or rock fragment); (iii) 'intercallations': elongate, undulating pedofeatures unrelated to natural surfaces or voids, not consisting of crystals. Fig. 4 shows some microphotographs of pedofeatures not related to surfaces or voids.

The last type of pedofeatures are 'Excrements' (mainly of the mesofauna), subdivided according to their shape, such as spheres, ellipsoids, cylinders, tuberoses or mamillated. Their description also comprises their degree of disintegration or coalescence and aging.

'Compound pedofeatures' are a combination of two or more features that can be 'juxtaposed' (e.g., a calcite coating over a clay coating) or superimposed (e.g., an Fe-oxide nodule developed in a clay coating). Pedofeatures often are fragmented (e.g., by freezing), deformed (e.g., by vertic movements) or partly dissolved.

Applications

The wide range of applications of soil micromorphology in earth sciences is variable in time. It is shifting from mainly pedogenesis and classification till the 1980s, to palaeopedology, quaternary geology and geoarchaeology last decennia. Also its practical application in agronomy is getting more important. Fig. 5 shows the evolution of the topics treated in papers containing micromorphology. For more detail, see [Stoops \(2014\)](#).

Soil genesis and paleopedology

Since its beginning, most of the research using soil micromorphology techniques has aimed to describe and understand the processes of soil and regolith formation. This results from the main paradigm of soil science that the morphological characteristics of the soils we observe today are mainly the result of particular soil formation processes that depend on the combination of various factors of soil formation. Therefore, the observation of their constituents and of their spatial relationships at a microscopic scale will provide information about the transformation, addition, removal, and translocation of soil constituents in the soil during its formation.

In most of the cases it is not possible to establish direct relationships between processes of soil formation and micromorphological features. For example, crumb microstructures can originate from faunal activity, but also by frost action. Likewise, silt cappings and coatings are characteristic of certain natric horizons, but they are also found in buried plough layers. Nevertheless, it is possible to assign sets of characteristic features to the outcomes of given soil formation processes, sometimes with the confirmation of additional laboratory analyses. With increasing research these relations have reached a consensus for some kinds of soil materials, while for others there is still some controversy. A compilation of the state-of-art interpretation of micromorphology for soil genesis is given in [Stoops et al. \(2018\)](#). Some of these processes with a summary of their resulting characteristics are listed below.

Pedogenic formation processes in arid soils: calcium carbonate, gypsum and salt dynamics

In contrast to other analytical techniques, micromorphology enables the distinction between lithogenic (inherited) and pedogenic (neoformed) constituents. The accumulation of pedogenic calcium carbonate, gypsum and salts occurs under arid climates because these minerals are not leached out of the profile. It results in calcitic, gypsic or saline pedofeatures, for example as nodules, coatings or infillings, which can be distinguished from the calcite or gypsum as lithogenic groundmass constituents. In the later stages of development, the maximum expression of this process is their generalized accumulation, with calcite, gypsum or soluble salt minerals becoming the main constituents of the groundmass. Additional characteristics, such as biocalcification, carbonate-depletion features, gypsum-mouldic voids or the presence of companion minerals like celestite are indicators of specific soil formation processes.

Processes in acid sulfate soils

Soils containing sulfidic or sulfuric materials are common in some coastal lowlands as well as in specific inland environments. Their dynamics result from alternating wetting and drying, water table oscillation and the mixing of continental and sea water, as well as

Fig. 4 Crystals and nodules. (A) Loose continuous lenticular gypsum infillings in a soil on alluvial fan deposits near Lleida, Catalonia. PPL. (B) Same in XPL. Note calcitic crystallitic b-fabric in groundmass. (C) Iron nodules in groundmass with porphyric c/f related distribution pattern. Clayey soil on basalt, Galápagos. PPL. (D) Same in XPL. Note the granostriated b-fabric around nodules, created by parallel orientation of the clay particles due to pressure. (E) Plagioclase in basaltic scoria altered to Si-Al colloids. Soil with andic properties, Galápagos. (F) Same, XPL. It is clear that in the phenocryst the colloid is partly crystallized to gibbsite, not in the microlites.

anthropic changes in drainage. The processes involve redox transformations of Fe and S, dissolution of Ca-bearing constituents, and the neoformation of minerals such as pyrite, jarosite, various iron oxides or gypsum, among other changes. Micromorphology enables the identification of these transformations and constituents, and of their spatial relations to organic matter and to the pore system, which is not possible with other techniques.

Fig. 5 Evolution of the application fields of micromorphology expressed in % and/or the total number of publications (partly based on the database of Stoops, 2014).

Clay illuviation

This process was the first to be identified through micromorphology, because the main characteristic feature of this process, microlaminated clay coatings, is easily identified in thin section. Coatings of microlaminated clay around sand grains or along pore walls that originated from the deposition of illuviated clay show interference colors under crossed polars. They result from the continuous parallel orientation of the clay flakes, which is different from the unoriented clay in the groundmass. The micromorphology of clay illuviation can indicate different types of clay coatings resulting from different conditions, such as the clay size, sorting or layering within the coating. It also shows their spatial relations with the pore system, which indicates whether clay illuviation is active or relict, and whether they are altered due to changing conditions. Soil micromorphology enables us to distinguish coatings around pores or ped faces from pressure faces due to swelling and shrinking of clays, for example, which is not possible in field profile descriptions. It is also the only technique that can distinguish between clay coatings formed by physico-chemical processes, and those resulting from gravitational transport, such as flood coatings.

Redox processes

The identification of redoximorphic features is an important part of routine soil profile descriptions, and is a diagnostic feature of drainage conditions. The morphological changes due to the redox status of the soil constituents mainly affect Fe (iron) and Mn (manganese). Micromorphology can help to identify the neoformation of minerals containing these elements and their relation with the pore system, which can be alternately aerated or filled with water. There are many redox pedofeatures (e.g. different types of nodules, coatings, hypo- and quasi- coatings, Fe-depletion features), which either alone or in combination give information about the intensity of the redox process, whether it is active or relict, or about its temporal relation with other soil forming processes.

Bioturbation

The result of faunal activity in thin sections is seen either by the presence of specific types of pores due to animal excavation (channels, chambers), by passage (fabric) pedofeatures resulting from their circulation through the soil, by the different types of excrements, formed by mineral and/or organic soil constituents, or by specific types of aggregates such as crumb or granular microstructures. The expression of bioturbation is extremely variable in size, morphology and related distribution to organic residues depending on the taxa; its complete description can give information about their feeding and displacement habits. Micromorphology can determine the extent of bioturbation by the fauna responsible for porosity and structure, mostly macro- and meso-fauna, and also the degree of mixing between mineral and organic constituents. Although it is possible in only a few cases to assign some features unequivocally to a given taxon (e.g., some biocalcifications by earthworms, or herbivores), in most cases the possible organisms producing excrements with a specific size and morphology can be determined with some degree of precision.

Frost action

The formation of ice in soils, either present or past, imprints specific morphologies in soils mainly due to the volume increase of water when passing from liquid to solid, to the desiccation associated to ice segregation, and also to the change in drainage conditions when a complete horizon is frozen, either temporarily or permanently. Some microfabrics are specific to soils subjected to glacial or periglacial conditions, such as the lenticular microstructure produced by ice lensing, sand and or silt cappings with

inverted sorting, and some injection features or vertical alignment of coarse fragments. In other cases, it will be the combination of several pedofeatures that will serve as diagnostic of frost action, such as silt cappings on 'floating' coarse fragments (underlain by a pore), ice-fragmented constituents, vesicular porosity, grano- and poro-striated b-fabrics due to stress by increased ice volume or some non-biogenic granular structures. The identification of cryogenic microstructures as in cave sediments has been useful for geoarchaeologists and quaternarists to determine past cold climates.

Argilloturbation

Clay shrinking and swelling due to moisture changes in soils is expressed in the field by a characteristic structure and fissure pattern, and by slickensides, which are indicators of vertic properties and vertisols. The most common micromorphological features are angular blocky microstructures with well-accommodated (recent) planes, and striated b-fabrics (mainly poro-, grano-, cross-striated). Other additional features can be granular microstructures at the surface (corresponding to the self-mulching), evidence of rotation and fragmentation of coarse fragments, nodules and other pedofeatures, and incorporation of clay coatings in the micromass (e.g., in Mediterranean soils).

Podsolization

The translocation and accumulation of complexed organic matter, Fe and Al (aluminium) in soil is expressed by different morphologies depending on their position in the profile. Micromorphology can identify these processes when they are not evident in the field, mainly in spodic soil materials. The accumulation of amorphous (isotropic, opaque) organic matter with Fe and Al in a sand results in different types of c/f related distributions depending on whether the OM coats grains (chitonic), forms bridges or aggregates between them (gefuric or enaulic) or completely fills the spaces between them (porphyric). The internal fabric of the organic constituents (monomorphic or polymorphic) gives clues on their origin, either translocated or in situ. Because of the isotropic nature of organic matter, additional analyses are necessary for the complete characterization of spodic soil materials.

Formation of oxic or ferrallitic materials

These result from extreme weathering under moist, hot tropical conditions. Only the most resistant minerals (quartz, zircon) will survive, together with a variety of Fe and Al oxides and hydroxides with kaolinite as dominant clay. The most common micromorphological characteristics are a reddish-yellowish groundmass with a granular microstructure, an undifferentiated (due to Fe oxides) or stipple-speckled b-fabric, and the dominance of quartz in the coarse fraction, which may show incipient weathering stages (runiquartz).

Finally, paleopedology, defined as the discipline of soil genesis deals with soils formed in past environments, benefits considerably from micromorphology for identifying the soil forming processes that no longer relate to present conditions. Polygenetic soils, buried or not, formed under a succession of different soil forming factors and will show superposition of those features that are characteristic to each of them, as if they were medieval palimpsests. In this way it is possible to establish the relative chronology of the processes and possibly the sequence of soil forming factors that led to them. Together with the appropriate dating techniques, it is possible to reconstruct paleosedimentary records, especially in Quaternary formations. Loess-paleosol sequences are perhaps the best known examples of buried soils since the Late Tertiary, because the accretion of deposits and their homogeneous composition allow soil formation processes to be clearly expressed and differentiated at depth. The observed features result from the succession of cold/mild/warm and humid/dry climates together with the associated vegetation during the Quaternary. The features include clay illuviation, calcitic and gypsic pedofeatures, accumulation of organic matter in buried A horizons, rubefaction, and different types of cryogenic features the main paleoenvironmental markers.

Soil classification

With the older, natural soil classifications, such as that of Kubiěna (1953), there was a close link between soil types and their micromorphological aspects. This link was lost with the morpho-analytical thin section descriptions and current soil classification systems, mostly based on quantitative chemical, physical, morphological, mineralogical and climatic data. Therefore, soil type can no longer be derived from its micromorphology alone, because the relationships between the micromorphology and their overall classification are no longer possible because of the many characteristics considered when classifying them.

Nevertheless, the two international classification systems (Soil Taxonomy and the World Reference Base for Soil Resources) were initially conceived as morphogenetic systems, where morphology and micromorphology were used as markers for soil genesis. Micromorphology played a role in the development of the American Soil Taxonomy, especially for argillic, spodic and cambic horizons. Micromorphological features were in general not used as criteria, but as a guide for selecting criteria because of their value in determining the direction of pedogenic processes.

At present, micromorphology is only explicit in the definition of argillic (Soil Taxonomy, Soil Survey Staff, 2014), argic (World Reference Base for Soil Resources, IUSS Working Group WRB, 2015), and natric horizons (both systems), for which evidences is required of illuvial clay, i.e., oriented clay, clay coatings and or "thin sections with oriented clay bodies in more than 1% of the section" in both systems. Even with a hand lens in the field it is impossible to discern whether observed coatings are composed of clay or of coarser fractions, but micromorphology enables this and is the most used technique to diagnose clay illuviation for soil classification (Stoops et al. 2018, ch. 14 and early papers on soil micromorphology).

Some diagnostic soil characteristics for classification require the use of micromorphology, such as for the calcic horizon, defined as an “illuvial horizon, in which secondary calcium carbonate or other carbonates have accumulated to a significant extent”. Secondary carbonates are best identified and characterized in thin section, as calcitic pedofeatures, which can be distinguished from groundmass calcite belonging to the parent material (Stoops et al., 2018, ch. 9), whereas chemical analyses of carbonate content cannot differentiate between them.

Similarly, gypsic diagnostic horizons are defined as those horizons where “gypsum has been accumulated or transformed to a significant extent” in the classification systems. The identification of gypsic pedofeatures in thin section becomes an unequivocal proof, regardless of whether the quantitative requirements are fulfilled. The World Reference Base for Soil Resources (IUSS Working Group WRB, 2015) explains, in detail, the micromorphology of petrogypsic horizons in its additional characteristics.

Redoximorphic features, one of the indicators of aquic conditions, are morphological features that can be observed in the field, but it is in thin sections that they can be described in detail. Redox concentrations, redox depletions and reduced matrices can be characterized not only as presence or absence, but in relation to the pore system and biological activity, and also determine whether the redoximorphic features are currently active or relict (Stoops et al., 2018, ch. 15). Micromorphology can identify gleyic or stagnic redoximorphic patterns (IUSS Working Group WRB, 2015) since they are defined in relation to present porosity. Stoops et al. (2018, ch. 15), established seven degrees of redox conditions according to different combinations of redoximorphic pedofeatures observed in thin section.

The classification of organic layers as humus profiles relies mainly on morphological and laboratory data, but combined with their micromorphological characterization it is possible to assign sets of micromorphological features to given humus types (Zaiets and Poch, 2018).

Geomorphology and quaternary geology

The most important geomorphological processes studied using micromorphology are weathering, erosion and sediment deposition (for more detail see Stoops et al., 2018).

Micromorphological studies combined with chemical and mineralogical analyses allow a better understanding of present or past weathering processes and their relative chronology. Several features that can be detected only by micromorphology are the relation between porosity and weathering patterns, the development of new porosity (e.g., mouldic voids), or the successive phases of mineral alteration, including the transformation of earlier alteration products (e.g., feldspar → Si-Al-colloids → gibbsite).

Erosion is detectable in only a few cases by microscopic analysis (e.g., tillage erosion), but it can be indirectly deduced from the sedimentary deposits. In colluvial deposits laminated and non-laminated fabrics are distinguished. Mass-wasting deposits comprise solifluction deposits, landslides, debris-flow deposits and grain-flow deposits. Interpretation is based partly on micromorphological studies during field or laboratory experiments, such as artificial rain plots or wind tunnels. Their internal fabric provides information on the conditions under which the processes were active (e.g., frost) and the material transported (e.g., eroded soil). Locally, wind deposits are also important in landscape formation (e.g., sand and loess deposits) and can be detected in thin sections. Post depositional alteration may yield information on later processes including interruptions during which pedogenesis took place.

Since the early 1990s micromorphology has often been used in Quaternary geology. It has proved to be very efficient for the analysis of glacial and fluvioglacial deposits (see Van der Meer and Menzies, 2011). A terminology based on Brewer, (1964) is mostly used.

Agronomy

Agricultural practices that can leave an imprint on soil micromorphology are tillage, irrigation, addition of materials to increase soil fertility, burning, waste recycling, clearance and husbandry (Stoops et al., 2018, ch. 26). Some of the effects can be detected through morphological (field), chemical or physical analyses, but micromorphology can provide explanations on the soil's behavior, even when the processes are incipient or are not yet reflected in other properties (Stoops et al., 2018, ch. 1). These effects are mainly explained by (1) changes in microstructure, (2) presence or absence and location of some constituents (both as coarse or fine constituents and as pedofeatures), and (3) changes in the activity of soil biota.

One of the main questions in the interpretation of features due to agriculture is whether they are unequivocally due to it, or whether the same features can be caused by natural processes. This is the case, for example with silt cappings and coatings on pores, which can be result from both periglacial processes and disturbance by ploughing. Therefore, their interpretation must always be made with caution.

Tillage practices change the amount, type and distribution of pores and aggregates. The clearest effects of ploughing and tillage are a temporal increase of porosity in the topsoil, the formation of dense plough pans with laminar structure (Stoops et al., 2018, ch. 26) or compaction by traffic at the surface. While these effects can be quantified by physical methods, micromorphology also provides information about types and functionality of pores, and changes in type and size of aggregates or degree of pedality. For example, tilled soils compared with untilled, natural or forested soils may show changes from a crumb microstructure due to bioturbation to a subangular blocky structure because of a reduction in faunal activity. In frost-affected environments, the interaction between tillage and freeze-thaw processes was studied by Sveistrup et al. (2005) who reported an increase in bioturbation when forest changed to cropland.

Surface crusting and sealing is another area where micromorphology has contributed considerably to explaining the mechanisms of formation, because of the inherent difficulties in sampling for other types of analyses. Thin sections enable the distinction between structural and depositional crusts (Stoops et al., 2018, ch. 19), and can provide information about the causes of crust formation, such as the slaking of aggregates. Fragments of surface crusts and of silt coatings around pores formed after the collapse of aggregates has been used as a diagnostic feature for identifying buried Ap horizons.

Soil micromorphology can help to explain the effects of the application of fertilizers and amendments in soils from changes in aggregation and microstructure or an increase of faunal activity. The application of organic amendments as animal manure has a clear influence on soil microstructure, mainly with the increase of bioturbation (Yagüe et al., 2016). Chemical fertilizers may also have such an effect with the increase in nutrients or changes in pH, for example from liming.

Irrigation practices may change soil porosity patterns and create textural pedofeatures derived from the migration of fine particles with water after aggregate collapse or change in the composition of the exchange complex (Stoops et al., 2018, ch. 26). Redistribution of gypsum, carbonates and salts are other features commonly reported. Processes such as the silting of drains in irrigated sodic soils can be described and explained through thin section analysis. The analysis of redoximorphic pedofeatures in paddy soils may give information on the nature and intensity of redox processes.

Some particular soils with long-term anthropic influence have merited special attention among micromorphologists. For example, deeply disturbed soils and the effects of old tillage practices, on the Amazonian dark earths ('terras pretas do índio'), (Nicosia and Stoops, 2017, ch. 33); plaggen soils (Davidson & Carter, 1998; Múcher et al., 1990), bench-terraced soils in the Mediterranean (Boixadera et al. 2016), and soils on 'camellones' in the Bolivian Moxos plains (Boixadera et al. 2019).

Archaeology and geoarchaeology

Soil micromorphology offers a wide range of applications in archaeology (see Nicosia and Stoops, 2017) and its use by geoarchaeologists has increased since the end of the 1970s.

In paleoenvironmental studies micromorphology provides information on processes affecting archaeological sites (e.g., earthy constructions such as Tells), and on colluvial processes during and after occupation of the sites, often responsible for their burying. The materials filling manmade structures, such as ditches yield information on the processes involved and their relative chronology.

An important application is the reconstruction of past soil management practices, such as vegetation clearing and tillage, trampling and traffic effects and the formation of the so-called 'dark earths,' mainly studied in European towns and in South America.

The study of living or occupation floors, e.g., in houses or caves, yields information on activities such as metal working, manufacture of stone tools or butchery. Stable floors contain elements on the type of animals and their feeding habits.

One of the oldest applications of micromorphology in archaeology was the study of materials not commonly studied in natural soils, such as excrements of larger animals, bones, eggshells, phytoliths, charred material and plant ash and anthropogenic constituents such as plasters and mortars, ceramic materials (e.g., bricks, tiles and pottery) and metal working residues. The fabric study of man-made constituents helps in reconstructing the manufacturing processes, e.g., the preparation of mortars: what is the origin of the coarse material, was it sieved, what proportions coarse/fine were used, which type of limestone or shells were used to prepare the quick-lime, among other questions.

Forensic science

The application of soil science to forensic sciences, also referred as forensic soil science, is a fairly recent discipline that applies information related to the properties of soils in matters that may come before a court of law. It is commonly used to find evidence to link a suspect to a crime scene or to determine the state of decay (taphonomy) of any biological materials in the soil, including human remains.

A systematic approach to forensic soil examinations involves a thorough description and analysis of soil morphology (Munsell color, texture, structure, consistence), together with mineral and organic composition, for which micromorphological techniques are valuable (Fitzpatrick et al., 2009). The concept behind it is that soil composition can be used as a predictive tool to identify where that soil originated.

Soil science is very useful in the taphonomy of buried organic remains because the evolution of soil organic matter depends on soil characteristics (composition, drainage status, temperature, pH). For example, some researchers have tried to establish micromorphological indicators as presence or absence of certain compounds to characterize the time from the burials.

Conclusions and perspectives

There are several challenges in soil science where soil micromorphology has a great potential to contribute. One is the assessment of risks associated with new soil management techniques, such as the addition of residues as amendments. In particular, micromorphology can reveal interaction mechanisms of microplastics in soils, or the effects of the application of different types of sludges, how they evolve and how they interact with soil constituents or with soil microstructure.

Soils are important carbon sinks. In the framework of climate change, micromorphology can help to describe the dynamics of organic and inorganic carbon in soils, for example the evolution and transformation processes of organic matter, or the influence of irrigation on the dynamics of calcium carbonate as a source or sink of carbon.

We have some knowledge of the soil organisms, their functions and interrelations, but the interactions of soil biota with soil mineral constituents are still largely unknown. Experimental pedology, which attempts to reproduce the habitats for particular soil organisms under controlled conditions, is a promising research field for the interpretation of biotic features using micromorphological techniques.

As soil analytical methods evolve and new techniques are developed, there will remain a role for soil micromorphology in field and landscape surveys because soil morphology at any scale, including micromorphology, provides the spatial framework within which any further observations or analyses can be considered.

Abstract

The chapter describes the first attempts in Antiquity to differentiate between lands with certain soils, followed by the major developments in Dokuchaev's time when soil itself became the focus of classification. Soil-forming agents, soil processes and properties were interrelated in his system, and this was the source of two trends in choosing priorities by his successors. There were many individual author's classification systems and the criteria ranged from soil physicochemical properties to soil profile morphology and soil genesis. Almost all modern soil classification systems have been greatly influenced by Dokuchaev. Quite different systems have been developed on this basis throughout the world and are discussed briefly.

Key points

- Need for soil classification increases, and a regular updating of existing systems is required.
- First attempts to classify soils for applied purposes appeared in Antiquity. Then in the 18–19th centuries, a new outburst of classification activity may be noted.
- Dokuchaev's paradigm was a milestone in pedology. His predecessors and followers created an array of concepts on soil classification.
- Diversity of natural systems and divergence in classification principles: priority of soil-forming factors versus soil properties.
- However, in all systems, pedogenetic processes were accounted for although in different ways: minimal as diagnostic criteria, maximal as differentiating taxa.
- Development of an International system started in 1970s.
- Russian soil classification system is a properties-oriented one and has inherited Dokuchaev's pedogenetic approaches.

Introduction. Challenges of soil classification

"The general problem of Classification... may be stated as follows: To provide that things shall be thought of in such groups, and those groups in such an order, as will best conduce to the remembrance and to the ascertainment of their laws.... Each science... forms its classification of things according to the properties which fall within its special cognizance, or of which it must take account in order to accomplish its peculiar practical end" (Mill, 1882, pp. 870–874). In other words, classification is a contrivance to organize knowledge in our mind.

Knowledge about soils has been accumulated by humans since prehistoric times, and various soil classification systems have been created over time. They are based on the data already acquired; therefore, these systems considered in the historical perspective reflect the evolution of soil science and also possibly the related sciences of biology, chemistry, and physics. For example, the father of the American *Soil Taxonomy* Guy Smith stated: "classification is a creation of man and is a reflection of the state of knowledge at that time and the uses that were intended at that time" (Smith, 1986, p. 111). There is a similar saying of the famous Austrian pedologist Walter von Kubiřna (1948): "Show me your classification, and I will tell you what the state of your science is."

Soil classification systems differ in their purposes. Some of them address particular applied problems, e.g., soil suitability for septic tank construction, or soil suitability for grain crop growing, or soil physical behavior (classification of soil textures). Such classification systems consider a relatively narrow range of soil properties pertinent to a given purpose. These are technical, or applied, or artificial (as defined by J.S. Mill) classifications. Other systems address a much broader challenge to understand relationships between different soil groups, to map their geographic distribution, and to make justified assumptions about the actual and potential functions and uses of soils. They were named *Natural classification systems* by J.S. Mill, and are now referred to as fundamental or 'basic systems', or taxonomies. These are mostly hierarchical systems.

By giving appropriate definitions and names to soil taxa, classification ensures a common language and common understanding of soils, and eases communication between specialists in soil science, as well as in different fields of learning and working for people from different countries. A good soil classification system should have a predictive power, i.e., it should make it possible to predict unknown soils, their properties and functions. It should also be a guide in the search for new knowledge by addressing controversial relationships and finding appropriate criteria to differentiate soils.

As knowledge on soils is continuously accumulating, soil classification systems cannot remain static; they should be regularly updated or completely revised. New facts and data that cannot be explained within the framework of the existing classification serve as impetus for its change: from minor adjustment to a radically new paradigm. The development of classification is an endless process with certain stages. According to Vladimir M. Fridland, the intervals between such stages should be 10–15 years.¹

Almost all modern soil classification systems have been greatly influenced by a revolutionary perception of soil shaped in the last quarter of the 19th century by the Russian geologist Vasilii V. Dokuchaev: “soil is an independent (individual, separate, of its own) natural body, the product (later, function) of soil-forming factors (climate, relief, biota, parent material, and time).” This was a radically new definition of soil, simple and yet very comprehensive; it provided an excellent basis for classifying soils in accordance with either the soil forming agents, or soil properties, or both.

Different soil classification systems have been developed on this basis in Russia and throughout the world and are briefly discussed below; similarities and differences in the approaches and structure of these systems are analyzed. It is argued that, although recent major soil classification systems used in different countries have much in common, direct correlation between them is impossible. The *World Reference Base for Soil Resources* (WRB), which was initially designed as an umbrella for national systems and a bridge between them, remains a partial solution to the current incompatibility of soil classification systems (IUSS Working Group WRB, 2015).

Thus, pedology is still dreaming about creating a new universal soil classification system. The need for such a system is fostered by new demands related to the growing awareness of the key role of soils to the solution of pressing environmental problems and in sustaining life on our planet.

Indigenous soil knowledge and first soil classification systems

People live on soil and cannot but pay attention to this substrate in the support of their lives. It is probable that ancient hunters and gatherers knew different physical states of soils (wet, dry, loose, hard, soft, sticky, stony, etc.) and types of environments (hilly and plain areas, flooded areas, lowlands and highlands, mires, forests, steppes, etc.). The Neolithic Revolution about 10,000 BP and the birth of agriculture in the area now known as the Middle East shifted the focus of soil cognition to soil fertility and soil suitability for crop growing. It was also important to predict the response of soil to various ameliorative measures, including application of manure and irrigation. Numerous local soil names appeared in different parts of the world; many of them are still in use and have entered modern national and international soil classification systems. A new science, ethnopedology, has emerged recently at the interface of cultural anthropology and soil science to study folk soil knowledge (Krasilnikov et al., 2009).

In this context, almost all (ancient) human cultures and natural religions all over the world have soils/earth as essential element of worship in general represented as feminine “deity” directly indicating fertility. The German term “Mutterboden” is a good example.

Vernacular soil names reflect specific features of soils in particular localities with a focus on soil color (dark, light, whitish, gray, red), soil texture (clay, sand, silt) and physical conditions (hard, loose, cemented, excessively moistened, dry, cold), soil salinity, specific environments (soils of moors, meadows, of pine, oak or spruce stands), and soil suitability for growing particular crops (wheat (*Triticum aestivum* L.), barley (*Hordeum vulgare* L.), or oats (*Avena sativa* L.)). The notion and nomenclature of soil types in the Russian soil classification systems are often derived from the local folk soil names, such as Chernozem, Podzol, Solonchak, Solonetz, Gley. However, the same local soil name (e.g., Chernozem or black earth, or Belozem or white earth) could mean different soils in different places, which often led to misunderstanding (Krasilnikov et al., 2009).

The diversity of local soil names and the obviously different productive capacities of soils necessitated a formal classification of soils for agricultural and land inventory purposes based on soil productivity. This challenge required a broader geographic extent of soil examination that had already been realized in large ancient empires. One of the oldest systems was developed more than 4000 years ago in China, during the Yao dynasty (2357–2261 BCE) (Lee, 1921). The best grade of soils were the yellow, soft soils of Yung Chow (Shensi and Kansu provinces, semiarid to arid Northwest China), whereas the next best were the red, rich clayey soils of Su Chow (Shantung, Kiangsu, and Anhwei provinces, humid East China). The five-colored “sacrificial altar” established in 1421 CE, during the Ming dynasty, at Zhongshan Park in Beijing demonstrates clear knowledge of the geographic distribution of soils in China: the central yellow color is characteristic of loess soils on the Loess Plateau, blue color to the east corresponds to gley, black color to the north denominates chernozems in northeastern China, white color to the west signifies the development of saline and light-colored desert soils, and red color to the south is typical of tropical Ferralsols (Gong et al., 2003; Krupenikov, 1992).

In Ancient Greece, soil was one of the basic philosophical categories—basic simple elements along with fire, water, and air for Empedocles (494–434 BCE) and Aristotle (384–322 BCE). These elements were shaped from the same prime matter by a spirit endowed with reason and were carriers of active (heat and cold) and passive (dry and wet) qualities. For Theophrastus (371–287

¹The American system is a good example: its main issues were in: 1954, 1960, 1975, 1999, 2014.

BCE), who was named the father of botany by Carl Linnaeus (1707–1778), soil was a more “earthy” matter. He made a distinction between soils of plains, mountains, valleys, seashores; differentiated soils by color and thickness; paid attention to soil textures; and considered soil suitability for particular crops (Strzemska, 1975).

In the Roman empire, a classification of arable soils based on farming utility with nine major classes and 21 subclasses was described by Marcus Porcius Cato (234–149 BCE) in his book *De Agri Cultura*. As noted by M. Strzemska (1975), the works of Roman agriculturalists Cato, Marcus Terentius Varro (116–27 BCE), Lucius Junius Moderatus Columella (4–70 CE), and Gaius Plinius Secundus (23/24–79 CE) were “the pillars of soil science not only in the antiquity but also in the Middle Ages and early modern times.” Thus, Cato considered the suitability of soils for farming and their productive potential, Varro paid attention to the physical composition (texture, stoniness) of soils, Columella focused on the physical properties of soils, and Plinius regarded minerals and rocks as soil-forming materials.

As shown by B. Williams (2006), good knowledge of soils was also gained by the Aztecs. Many other interesting stories about the accumulation of soil knowledge over the millennia throughout the world are collected in the same book edited by B. Warkentin.

The European Middle Ages and Renaissance periods were marked by growing knowledge of soils and methods of soil management (Krupenikov, 1992; Strzemska, 1975). However, no considerable new concepts in the field of soil classification were achieved. An important innovation noted by M. Strzemska was the division of soils into (a) natural (vulgar) and (b) artificial (precious) by W. Folkingham in his *Feudigraphia* (1610) with a further subdivision of natural soils into simple and composite according to their main constituents.

Dokuchaev's immediate predecessors in the field of soil classification

‘A new wave’ in the study of soils, acquisition of new knowledge on them, laboratory experiments, and extensive geographic exploration of little known lands arose in Europe in the 18th–19th centuries. It was greatly influenced by the advances in chemistry. Fruitful debates on the major sources of plant nutrition, either organic (humus) or mineral, and the development of methods to determine the contents of different humus substances and the chemical elements in soils provided abundant data. The German agronomist Albrecht Thaer (1752–1828) considered soil as an unconsolidated substrate comprising mineral substances and humus. His agronomic classification of soils (1810) was based on their division into classes according to texture and mineralogy with an indication of a soil’s suitability for major crops (wheat, barley, oats). It was widely applied in European countries. In particular, it was used in questionnaires sent to landowners and local authorities, on the basis of which the first soil maps of European Russia were produced in the middle of the 19th century. In the soil map compiled by Vasilii Chaslavsky (1834–1878) in 1875 and based on data from local sources, the legend included 32 soils.

After the sudden death of Chaslavsky (in 1878), Vasilii Dokuchaev (1846–1903) was entrusted to prepare explanatory notes for this map. This was realized in a fundamental Dokuchaev’s publication *Cartography of Russian Soils* (1879), in which the framework of the new concept of soil was suggested. Dokuchaev emphasized the complicated and in some cases chaotic pattern of soil distribution on the map, although zonal regularities could be traced, and he argued that a new soil classification system was needed to deal with the real soil diversity.

In his review of major soil classification systems (1886), Dokuchaev analyzed the “chemical” classification of soils by the German agronomist Wilhelm Knopp (1817–1891) with a major division into silicate, calcareous, and sulfate soils and the “petrographic” classification by the German lawyer and tax assessor Friedrich Albert Fallou (1794–1877), who also coined the term “pedology”. Fallou stated in his monograph (1862) that soil is the product of mineral and rock weathering. He analyzed manifestations of weathering processes in different kinds of rock. At the highest level, soils were classified into primary (sedentary) and transferred soils with further division into petrographic genera (soils of quartz, clay, mica, feldspar, marly rocks, etc.). In 1882, Ferdinand von Richthofen (1833–1905) suggested a somewhat different system with the division into eluvial (primary) and transferred soils at the highest level and to different kinds of parent materials at the second level. The distinction between in situ (sedentary, eluvial, non-transferred, primary) and transferred soils (sediments) was most important for the German geological school of thought in soil science.

The agrogeological approach to soil classification advanced by German scientists quickly spread throughout the world in the 1860s–1890s. In the United States, this spread was greatly facilitated by the fact that the first work on soils was conducted by geologists. In a review by George Coffey (1875–1967), the reports by Amos Eaton (1776–1842) and Theodric Romeyn Beck (1791–1855) on the soils of Albany county (1820) and then on Rensselaer County, New York (1822) and districts adjoining the Erie Canal (1824) are mentioned as the first attempt to classify the soils of the United States with a major distinction between unmoved soil and soil conveyed by water (Coffey, 1911).

Perhaps, the most significant contribution to shaping American soil science in that period belongs to Eugene Hilgard (1833–1916). Being educated in Europe and investigating geological conditions, topography, and agriculture in Mississippi (1860) and then in Michigan, California, northwestern states, and the Pacific Coast, Hilgard indicated the relationships between soils and climate. He understood the difference in the nature of soil formation in arid and humid regions, and explained the appearance of salinization in arid regions (Hilgard, 1892). In his views on soil classification, Hilgard followed the agrogeological approach separating soils into divisions of (1) sedentary (residual) and (2) transported soils; in the latter, he distinguished between colluvial and alluvial soils and assumed the presence of various intergrades between these classes.

Another characteristic feature of the American approach to soil classification in that period was a keen attention to soil texture and related physical properties. Their importance for agriculture was emphasized by Milton Whitney (1860–1927) in his paper of

1892. In 1890, regular soil surveys on a large scale were initiated by the Division of Soils (in 1901–1927, Bureau of Soils) headed by Whitney. Initially, the soils of surveyed areas were grouped into soil types based on texture. Then, the concept of soil series as a set of soil types derived from the same kind of geologic material came into force. In the first national soil map (Whitney, 1909), soil series were grouped into 14 provinces based on geology and climate (Simonson, 1989; Brevik and Hartemink, 2012).

Thus, the agrogeological approach to soil classification predominated in the world at the turn of 20th century; it was partly due to the international activity of German scientists. Max Fesca (1846–1917) from Germany worked as a foreign advisor to the Meiji Government in Japan in 1882–1894 and conducted the first soil surveys there; parent material, texture, and the organic matter content were the main criteria for differentiating soil units (Hirai and Hamazaki, 2004). Ferdinand von Richthofen brought the German experience to China. The first two international soil science congresses in Bucharest (1909) and Stockholm (1910) were named Agrogeological congresses.

Dokuchaev's paradigm, the genetic approach to soil classification

As noted in the review of existing soil classification systems by Dokuchaev (1886), these systems: (i) consider soil from different viewpoints (chemical, physical, geological, agricultural) instead of giving the definition of soil per se as an individual natural body; (ii) do not pay attention to the fact that many soil properties are tightly linked to particular climatic, relief, geological, and vegetative conditions; and (iii) give preference to some artificially selected soil properties instead of classifying soils on the basis of the integrity of properties. He criticized the focus of the agronomic approach to soils on the upper fertile layer only, as well as the focus of agrogeologists on the parent material.

Dokuchaev suggested that a natural scientific classification of soils as individual natural bodies should be based on their genesis as related to soil-forming factors. He advanced the concept of the soil profile as the A–B–C system of horizons. His ideas predetermined the further development of soil classification in Russia and abroad. Initially (1879), Dokuchaev subdivided the universe of soils into two groups: (Group A) 'normal soils': soils formed in situ, and (Group B) 'abnormal soils': soils beyond the place of their origin. This division was similar to that suggested by agrogeologists. However, further division was based on the pedogenic properties. Normal soils were subdivided into classes of terrestrial 'vegetative' soils (soils developing under normal aeration conditions and not affected by groundwater) and terrestrial 'swampy' soils (soils developing under poor aeration conditions; soils affected by groundwater). Abnormal soils were subdivided into classes of outwashed (eroded) and inwashed (aggraded, sedimentary) soils. Several soil types with different properties were separated within the class of terrestrial vegetative soils. In 1886, Dokuchaev modified this system and added the group of transitional soils (Table 1).

Thus, at the highest level, Dokuchaev paid attention to the manner of soil occurrence, namely, sedentary or translocated soils, which depended on the relationships between pedogenesis and geodynamic processes. At the second level, soil hydromorphism was taken into account for normal soils and the trend of geodynamic processes for transitional and abnormal ones. At the third level, the nature of pedogenesis manifested itself in soil color, morphological and chemical soil features served as differentiating criteria.

In 1899, Dokuchaev forwarded the idea of natural horizontal and vertical zonality in the world of soils. It was a brilliant geographical concept. The concept of natural zonal regularities in the pedosphere was very attractive for many specialists in the Earth sciences. Dokuchaev's disciple Nikolay Sibirtsev (1860–1900) introduced the zonal perception of soils into the classification scheme. At the highest level, he divided all soils into classes: (i) 'zonal soils', or full-profile mature fine-earth soils forming continuous zones on the Earth's surface and developing under the impact of zonal (climate and vegetation) soil-forming agents; (ii) 'intrazonal soils' that appear within soil zones due to the effect of some specific local factors, such as parent material; and (iii) 'azonal', or immature soils with profiles that are not fully developed.

The following types of zonal soils formed the system of Sibirtsev (1895, 1900): (1) Lateritic (red earths); (2) Aeolian—dust (loess); (3) Desert-Steppe; (4) Chernozemic; (5) Gray Forest; (6) Soddy-Podzolic; and (7) Tundra soils. Intrazonal soils comprised

Class 1. Terrestrial "vegetative" soils: a. Light-gray northern soils b. Gray soils (forest soils) c. Chernozemic soils d. Chestnut soils e. Brown solonchic soils Class 2. Terrestrial "swampy" soils (meadow soils) Class 3. Typical swampy (bog) soils	Class 4. Outwashed (eroded) soils Class 5. Partly inwashed (aggraded) soils	Class 6. Aggraded soils (alluvial or aeolian sediments)

Fig. 1 Schematic map of soil zones of the northern hemisphere.

the types of: (1) Solonchaks; (2) Bog (Peat); and (3) Mucky-Calcareous (Rendzic) soils. Azonal soils were separated into subclasses of non-riparian soils with the types of skeletal and coarse-textured (dune) soils and floodplain soils with the type of Alluvial soils. Thus, at the highest level, this classification puts emphasis on soil-forming factors (mainly climate) and on the geographic pattern of soil distribution rather than on soils themselves. It can be referred to as the first factor-genetic system, and this principle was inherited by many soil classifications in Russia. The next step was Dokuchaev's classification scheme for soils of the northern hemisphere with concise descriptions of typical zonal soil-forming conditions and characteristics of zonal pedogenetic processes. In this scheme, the initial concepts of normal, transitional, and abnormal soils were considered as synonyms for those of zonal, intrazonal, and azonal soils, respectively. This system was implemented in a map developed by Dokuchaev for the World Exhibition in Paris in 1900 (Fig. 1) and became the 'trademark' of Russian small-scale soil mapping.

Post-Dokuchaev early period. Diversification of classification decisions and dissemination of Dokuchaev's ideas over the world

The first decades of the 20th century were marked by an impressive diversification of soil classification decisions in Russia. In fact, almost all prominent Russian pedologists suggested their own soil classification systems. Some ambiguity in the factor-genetic approach to soil classification was quite obvious to the followers of Dokuchaev. There were several attempts to make the classification "closer to the soil", i.e., to basic classification derived from soil properties rather than based on soil-forming factors.

Konstantin Glinka (1867–1927), the leader of soil geography in Russia, in his first textbook (1903–1904), had stressed that the concepts of zonal, intrazonal, and azonal soils should be considered as geographical rather than classification concepts. He noted that some isolated areas of Chernozem soils could occur in the forest zone and, in this case, should be placed into the category of intrazonal soils. Thus, the same soil (Chernozem) can be found in two different groups of soils (zonal and intrazonal) at the higher level of ‘zonal’ classification, which is inconsistent with the rules of any classification. Glinka was the first to revive J.S. Mill’s ideas on the theory of classification and introduce them into pedology. The German edition of Glinka’s textbook in 1914 (Glinka, 1914) and its English translation by Curtis Marbut (1863–1935) published in the United States in 1927 greatly facilitated the worldwide dissemination of Dokuchaev’s ideas.

In 1903–1908, Glinka proposed the subdivision of soils by soil-forming agents into ectomorphic soils, whose features are specified by external (climatic) conditions, and endomorphic soils, whose features are very strongly influenced by the properties of the parent material. In his latest publications (1921–1927) Glinka placed the types of pedogenesis at the highest taxonomic level: Lateritic, Podzolic, Steppe, Bog, and Solonetzic types of pedogenesis; they were further subdivided into 25 soil types. This was the first profile-genetic classification.

Georgiy Vysotskiy (1865–1940) tried to improve Sibirtsev’s classification by introducing the factors of relief and parent materials. He suggested that zonal soils should be defined as soils of particular climatic zones developing on flat surfaces composed of loamy sediments. Intrazonal soils were subdivided into subclasses: (i) soils that become zonal in neighboring climatic zones; (ii) absolutely intrazonal soils (affected by groundwater or by surface water that has stagnated in depressions); (iii) skeletal soils. Azonal immature soils were subdivided into subclasses of denuded (eroded) and aggraded (accumulative, sedimentary) soils. Vysotskiy (1906) distinguished between the soils of flat well-drained warm sites (soils of southern slopes that become zonal in a more arid climate) and poorly drained cold sites (soils of northern slopes that become zonal in a more humid climate). This was a factor-genetic classification with emphasis on topography and climate.

The idea of analogous soil series under different climatic conditions was developed by Yakov Afanasiev (1887–1937). Afanasiev’s classification was based on the idea that analogous combinations of parent rocks, topography, and vegetation can occur in different climatic zones, resulting in the development of analogous series of soils in these zones. Climatic zones were differentiated by temperature (cold, temperate cold, temperate warm, subtropical, and tropical) and by climate continentality. The resulting cells of the classification table were then subdivided into columns with different vegetation types (forest, forest-meadow, grasses) and rows presenting different kinds of parent material (silicate, calcareous, saline). It was a climate-oriented factor–genetic classification. The English translation of Afanasiev’s paper on the Russian soil classifications (Afanasiev, 1927) was an important event because it made it possible for English-speaking researchers to be aware of novel Russian approaches to classifying soils.

Sergey Neustruev (1874–1928) developed an original classification of elementary pedogenetic processes; he also specified processes as automorphic and hydromorphic (affected by groundwater) at the highest level. Automorphic processes were subdivided into three classes by the intensity of transformation of the mineral mass of soils (strong, moderate, and weak). At the third level, the fate of residual products was considered. Hydromorphic processes were subdivided into subgroups with (1) the accumulation of precipitates from the groundwater and (2) the stagnation of water and development of anaerobic reducing conditions. This was a process-oriented substantive-genetic classification.

Konstantin Gedroits (1872–1932) tried to substantiate the separation of soils based on the properties of the soil adsorption complex (SAC). At the highest level, he distinguished between the groups of base-saturated soils (without H^+ ions) and unsaturated soils (with H^+ ions). The major types of pedogenesis (Chernozemic, Solonchakous, Solonetzic, Solodic, Podzolic, and Lateritic) were characterized with respect to the composition of exchange cations, the state of the SAC, and the redistribution of pedogenetic products in the soil profile (Gedroits, 1925). Gedroits believed that the further development of physicochemical studies would make it possible to expand his system, which can be referred to as a physicochemical substantive-genetic classification.

Petr Kossovich (1862–1915) and Boris Polynov (1877–1952) combined the substantive-genetic principle of soil classification with geochemical ideas. Kossovich subdivided soils at the highest level into classes of geochemically independent (autonomous) and dependent (subordinate, heteronomous) soils and characterized seven autonomous types of pedogenesis and four types of genetically related subordinate pedogenesis (Kossowitsch, 1911). Polynov (1933) emphasized the idea of consecutive stages of soil evolution in both classes. Autonomous (eluvial, automorphic) soils were subdivided into the groups of alkaline carbonate-containing soils and acidic soils. The types of pedogenesis within these groups were believed to be linked by evolution. For example, the group of alkaline eluvial types of pedogenesis included Primitive Alkaline, Pre-Chernozemic, and Chernozemic. Later, Polynov linked soil development to evolutionary stages of residual and accumulative crusts of weathering (Polynov, 1936). This was an evolutionary geochemical-genetic soil classification.

The zonal paradigm was strongly supported by American soil scientists in their ‘middle’ Curtis Marbut period, although the uppermost category in Marbut’s classification was properties-oriented—Pedalfers and Pedocals, meaning soils dominated by the behavior of iron compounds and those rich in calcium carbonates, respectively (Marbut, 1935). The next, most familiar American system introduced by Baldwin et al. (1938), was zonal with three classes at the highest level—zonal, intrazonal, azonal, thus repeating the early Dokuchaev–Sibirtsev scheme. The 36 great soil groups, arranged in the zonal order comprised soils similar to the Russian ones, and they had the same names (solonetz, solonchak, brown forest, tundra, chestnut soil, etc.). Some soil names included landscape components (desert, prairie, meadow, Alpine, semi-bogged).

Despite this diversity of soil classification systems, none of them was detailed enough to meet the needs of large-scale soil surveys that started in the former Soviet Union in the 1930s. For the readers worldwide, these studies remained little known. However, as shown below, gradual dissemination of Dokuchaev’s genetic paradigm over the world occurred in that period.

Post-Dokuchaev late period. Divergence of approaches. National systems. Authors' systems. Old and new Russian systems

The second half of the 20th century may be named the 'Golden age' of soil classification: the impetus given by Dokuchaev and his successors continued to affect the development of classification activity in many countries. These were France, Germany, the United States, USSR, Canada, Great Britain, Australia, China, Brazil and some other countries. The possibility of dual interpretation of Dokuchaev's paradigm was the reason for developing the factor-genetic and properties-oriented approaches, and they were implemented in diverse classification systems in the 1960s–1990s. This was the period of active discussions of approaches triggered by the appearance of a markedly new American system in the form of several approximations and two 'Soil Taxonomy' books (1975, 1999), the development of national and individual authors' systems, and the birth of the first International soil classification—the legend to the FAO World Soil Map (1974)—transferred later (in 1998) into the World Reference Base (WRB) for Soil Resources.

National systems were created, updated, correlated, and their number increased. They were supported by extensive terrain and analytical research on soils, soil surveys, and interpreting their results for diverse purposes, both scientific and applied. The latter was more obvious in the American system, specifically in its early versions (1954, 1960) while in the European systems this trend was weaker. In the European and Soviet Union systems, priority was given to soil genesis, soil-forming processes and factors; of less importance were soil properties.

The German pedological school is frequently described in textbooks as having an agrogeological background. However, it was particularly perceptive to new Russian ideas. Hermann Stremme (1879–1961) was personally acquainted with K. Glinka and helped him with the German edition of Glinka's book (1914). Stremme's upper-level classes, or groups of soils (biogenic, hydrogenic, lithogenic and orogenic) correlated with Dokuchaev's soil-forming agents. The later system of Eduard Mückenhausen (1965) was based on the ideas of Walter Kubiřna (1953) and included subaqueous soils together with terrestrial, hydromorphic, and bog soils, and these groups of soils comprise the upper level—Abteilungen (Orders). The system has seven taxonomic categories and is defined as a morpho-genetic classification (*Working Group on Soil Classification of the German Soil Science Society, 1997*). The second category—suborder (Classes) includes soil properties and soil dynamics, the result of the main soil-forming processes, which produce genetic horizons; their assemblages identify soil types, the central units of the system. Subtypes are intergrades between types or deviations from the central type, varieties are qualitative modifications of subtypes, and subvarieties are their quantitative variants. Texture is a criterion at the lowest level. The structure of the system, names of categories and even some differentiating criteria have much in common with those used in Russian systems (types, subtypes, varieties). Much attention was always paid by German soil scientists to gley (hydromorphic) soils, among which Stagnogley, Pseudogley and even Hangogley, Oxigley and Bleichogley (bleached gley) were identified (there are in total four types and 27 subtypes in the class of Gley soils), to semi-terrestrial and sub-hydric soils, to solifluction covers, and to coastal soils under the influence of tides. Arable and cultivated variants of soils are included in many soil types.

The German system is regarded as still incomplete, and its new version is expected. Urban soils and their classification received much attention in German soil science in early 2000s, and seem to be included in the updated system.

The history of the French classification is rather unusual: two systems with quite different approaches, principles, hierarchy, new soil names, and construction were created. The first 'old' system of Aubert and Duřhaufour (1956) was quite individual in addressing soil evolution, which is recorded in the type of soil profile development. It was represented schematically as a sequence of horizons: profiles AC → A(B)C → ABC → AEBC. Pedogenetic processes underlie the system, and soil-forming agents, such as parent material or climate, are used to differentiate and even name soils; some of them have also zonal names. The French system, like the German one, is hierarchical and has seven categories; although, unlike it, the differentiating criteria are diverse at the upper level. They include humus forms, mineralogical composition, hydromorphism, and salinity. Soil diagnostics at the type level are based on profile morphology rather than specific horizons. The new French system also designated for soils of the world was published in 1995 and 2008, it was entitled *Référenciel Pédologique*; its authors did not consider it a classification *sensu stricto*. However, the system is very detailed and is defined as non-hierarchical, although it has two levels. The first level is based on soil properties implemented into the diagnostic reference horizons, whose combinations create central images (*grands ensembles de références*). The genetic approach is clearly present at this level, but it is more evident at the lower level, where numerous qualifiers are added to central images—reference solums. For qualifiers, diverse soil properties were used including types of humus, analytical and landscape characteristics such as alpine, subalpine, and also human effects on soils. Both French systems may be regarded as flexible and oriented or underlain by pedogenetic concepts. The new system enables detailed qualification of soils by compiling unlimited assemblages of qualifiers for soil types.

In the United States, in early 1950s, as a reaction to the overestimated zonal bias in soil classifications of Marbut (1935), and of Baldwin, Kellogg and Thorp (1938), Soil Taxonomy was born, first as a series of approximations; its Seventh Approximation of 1960 became well-known in the world. However, at first it was not accepted unanimously, and the main criticisms were: formal approach, absence of pedogenetic concepts, strange and difficult nomenclature.² Nevertheless, an important achievement of Soil Taxonomy was the system of diagnostic tools, horizons, properties and materials, which was accepted by many developers of soil classification.

²In the Introduction to *Référenciel Pédologique* of 1995 soil names were considered as a reminder of "Alice in the Wonderland" by Lewis Carroll.

In the Soviet Union, several individual or authors' systems appeared in the second half of the 20th century. Together with the national systems for soils of the USSR and Russia, several classification systems were proposed by eminent soil scientists. Most of them concern the upper taxonomic levels, where soil scientists implemented their personal perceptions of the world of soils; these systems ended at the level of 'genetic soil type' (solonetz, chernozem, gray forest soil). They may be regarded as updated approaches originally put forward by scientists of the Early Dokuchaev period.

Maria Glazovskaya revised the ideas of Polynov and suggested a geochemical-genetic system (Glazovskaya, 1983), and on this basis in the 1990s she proposed a series of applied classifications of soils by their vulnerability and tolerance towards pollutants ('heavy metals', acid rain).

Vladimir Volobuev (1973) suggested a system of soil grouping based on the recognition of 11 types of soil humus (in terms of its humate or fulvate nature, base saturation and the rate of plant residue decomposition) combined with categories of mass transformation of the mineral soil (from bedrock to ferrallitic weathered mantle). These entries provided a separation of the classes of soil formation. Criteria for the next level were the types of biological cycle and the geochemical position of the soil. The further subdivision indicated zonal types of soil formation. His approaches were defined as priority of 'organomineral reactions'.

Victor Kovda combined the evolutionary and geochemical approaches to soil grouping. He tried to arrange a system of soils by the balance of substances in the course of soil evolution from the hydroaccumulative (subaquatic) stage, via various hydromorphic states to the automorphic one; at higher level, soils were grouped into soil-geochemical formations by several characteristics embracing soil properties, pedogenetic processes and environment (Kovda et al., 1967).

Innokentiy Gerasimov trying to support and promote the genetic trends in soil classifications suggested a system based on elementary pedogenetic processes, thus reviving the early scheme of his teacher Sergey Neustruev. Pedogenetic processes were arranged into major groups: (I) transformation of organic material, (II) transformation of the soil mineral mass, (III) migration and accumulation of mineral, organomineral, and organic products of weathering and pedogenesis, (IV) cementation, and deformation (V). Major groups comprised elementary processes (25 in total), which received their own codes, and soil horizons were characterized by the sets of processes shaping them; combinations of horizons produced soil types, and each type was presented by 'process codes' and 'profile codes', i.e., profile formula (Gerasimov, 1975). Thus, soil properties and pedogenetic processes served as the framework of the system, and profile formulae for soil types were later implemented into the new Russian system.

Vladimir Fridland developed a classification system as supervisor of the State project on the compilation of a soil map of Russia. This work started with a detailed program to describe the soil map; the text provided descriptions of the 205 soils in the legend (1972). Soils were described in terms of preliminarily defined horizons and properties. This huge cartographic project resulted in a basic soil classification comprising three components: profile-genetic, regime, and mineralogical-petrographic (Fridland, 1982). Full soil names were composed of three groups of qualifiers for each component; soil types remained central units in this system and were identified by the sets of horizons. The profile-genetic component of Fridland's system became a basis for the new Russian soil classification of 1997–2004–2008.

In Russia, there are now two classification systems in use. The official system of 1977³ embraces soils of agricultural and potentially agricultural lands of the USSR, while the new classification includes soils of the whole country as its object (Fig. 2).

Fig. 2 Areas in the Soviet Union/Russia showing which soils are presented in two soil classification systems.

³Its English translation was first published in Egorov et al. (1986).

The new system was published as consecutive approximations in 1997,⁴ 2004, and 2008. Both systems were developed in the V.V. Dokuchaev Soil Science Institute, both are hierarchical, and differ in principles and structure.

The prototype of the Soviet system of 1977 was created by I. Gerasimov, A. Zavalishin, and Ye. Ivanova in 1939. The uppermost and main taxonomic unit ‘soil type’, was defined as “a group of soils developing in similar conditions and characterized by common origin and common processes of the transformation and migration of substances, similar level of fertility”. Criteria for the categories below the type level were officially adopted in 1958 by the Ministry of Agriculture of the USSR, as well as the list of 110 soil types (1966) for large-scale soil surveys.

The ideology of the system comprised: (i) the zonal (‘bioclimatic’) approach presuming a determined position of soil types in the coordinate system of bioclimatic parameters, (ii) the degree of soil hydromorphism (automorphic, semihydromorphic and hydromorphic soils). These principles were very strict; some deviations (e.g., the appearance of soluble salts in a soil of the humid climate) were shifted down to the lower level, if not omitted as incompatible with zonal conditions. It was a very consistent and fully developed system.

The 1977 system has many advantages: it is detailed; quantitative criteria for soil subdivision at the lower classification levels were thoroughly developed; addressed soil-forming agents was valuable for soil survey, and soils of croplands were subdivided by the degree of their cultivation. It was applied for large-scale soil mapping of agriculturally suitable areas. A large block presented aridic and irrigated soils of Central Asian republics. However, it did not include soils of the vast cold and permafrost-affected regions of the Russian North and Siberia (Fig. 2), and this was one of the reasons for developing a new system.

The new Russian soil classification system (RSCS) inherited many elements of Fridland’s basic system (1982), namely: principles, genesis and properties, taxonomic structure, broad range of soils, priority of diagnostic horizons and properties; it is open, hierarchical, and should be updated every 10–15 years. The first version of RSCS appeared in 1997, and the next one was published in 2004. Advice on the contents (not principles!) of both versions have been taken into account for a shorter version in 2008 “Field Guide for Russian Soils”. Updating of the RSCS is now in progress (Khitrov and Gerasimova, 2021, 2022).

Unlike other soil classifications in Russia/USSR, the RSCS starts with the definition of soil, which is important for delineating the objects classified, in particular, artificial human-made, urban, and subaqueous soils. As an extension of the sphere of objects, a special group of solid-phase bodies is mentioned in the RSCS under the name “Technogenic Surface Formations”. In order to emphasize their non-soil nature, unusual clumsy names were deliberately given to them, for example, “artificrat” meaning an artificially made (fabricated) pseudo-soil construction. Addressing non-traditional objects coincided in time with the birth of the International Working group SUITMA⁵ (1998).

In the RSCS soils are classified according to their properties which have been formed by pedogenetic processes; environmental conditions may be considered only for explanations and descriptions. Hence, the basic principle of RSCS is similar to the background of the International WRB system, as well as the diagnostic tools for soil identification, diagnostic horizons and diagnostic properties. In the RSCS, soil types are central soil units, and lower categories remain almost unchanged compared with the system of 1977. Two higher categories were introduced: trunks and orders (Table 2). At the uppermost level, trunks, soils are grouped according to the ratio of pedogenesis to lithogenesis (i.e., parent material formation; Fig. 3) The majority of soils belong to the postlithogenic trunk; the synlithogenic trunk embraces alluvial, volcanic, and urban soils, while all kinds of thick peat soils comprise the organogenic trunk; primary pedogenesis is weakly manifested on hard rocks or artificial substrates.

Table 2 Taxonomic categories and criteria for classes in the new Russian soil classification system.

Category	Criteria	Example of a full soil name
Trunk	Pedogenesis-to-lithogenesis (peat formation included) ratio	Synlithogenic
Order	Similar major elements of the profile, similarity of pedogenesis	Alluvial soils
Type	System of diagnostic horizons	<i>Dark-humus^a</i> alluvial soil
Subtype	Modifications of diagnostic horizons, intergrades between types	Dark-humus alluvial <i>quasigleyic</i> soil
Genus	Base (un)saturation, salinity, presence of carbonates and/or gypsum	Dark-humus alluvial quasigleyic <i>carbonate-rich</i> soil
Species	Degree of diagnostic property manifestation	<i>Deep</i> dark-humus alluvial quasigleyic carbonate-rich soil
Variety	Texture, amount of stones	Deep dark-humus <i>shallow</i> alluvial quasigleyic carbonate-rich loamy soil
Phase	Parent material, depth of the solum	Deep dark-humus shallow alluvial quasigleyic carbonate-rich soil <i>on finely stratified alluvium</i>

Example of alluvial soil (Fluvisol).

^aItalicized are qualifiers added to the soil name at the corresponding category.

⁴English translation edited by R.W. Arnold with some corrections was published in Shishov et al. (2001), prior to the main versions.

⁵SUITMA—Soils of Urban, Industrial, Transport, Mining/Military Areas.

Fig. 3 Soil horizons and parent materials in the trunks—upper category in the RSCS.

Table 3 Groups and number of diagnostic horizons in RSCS, WRB and US Soil Taxonomy (horizons of tropical soils in the WRB and Soil Taxonomy are excluded in this calculation).

Groups of horizons	Classification systems			
	Russian, 2008	Russian, proposed (2021, 2022)	WRB, 2014	Soil Taxonomy, 1999
Upper organomineral, humus- accumulative	11	10	5	4
Upper organic, accumulation of organic material	6	7	2	2
Transitional subsurface, destruction and removal of matter	5	5	–	2
Middle-profile, accumulation and transformation of matter	17	14	22	15
Hydrogenic, effect of ground water	4	2	–	–
Halomorphic, soluble salts in the solum	2	2	1	1
Human-modified and anthropogenic	6	6	5	2
Reclamation by filling	–	2	1	–
TOTAL	51	48	36	26

Criteria for the next category, order, are soil-forming processes in the broad sense. They are recognized by the character of the profile composition, or by a diagnostic horizon common to all soils of the order. Thus, orders of texturally differentiated, humus-accumulative, and alluvial soils may serve as examples. The classes of the third category are 'genetic soil types'. Soil type is defined as a soil body with a certain sequence of diagnostic horizons, or profile formula; consequently, each soil type has its own formula written in Roman capitals. These formulae are complemented by symbols (Roman lower-case letters) corresponding to diagnostic features serving as criteria for the fourth category, subtypes. There are four lower categories after the subtype, and they retain their names given in 1977: genus, species, variety, phase (Table 2).

Diagnostic horizons are important in the new system. Soil genesis underpins the choice of differentiating criteria and control of horizon definitions, which is similar to the WRB and US Soil Taxonomy (Soil Survey Staff, 1999), whereas the horizons themselves are close in their nature (Table 3) but not identical.

Diagnostic features are mostly modifications of genetic horizons produced by the overlay of several mechanisms responsible for horizon development, imprints of present-day soil regimes, or inheritance of former pedogenesis, including the human-affected events. To facilitate their application, they are grouped in accordance with their origin: process-derived, intergrades, evolutionary, rock-inherited, substrate-accumulative, etc.

Special attention is paid in the RSCS to human-modified soils, which are considered to be the result of soil evolution under the impact of human activities, mostly agricultural. Several stages of agrogenic evolution are specified; they are identified by the occurrence of human-modified horizons and features, and are reflected by the position of soils in the system. Thus, strongly modified soils form individual orders (second level); however, they are not analogues of Anthrosols. Moderately modified soils (with one new horizon and the remainder of the natural profile) are qualified as types within natural soil orders, whereas weakly modified ones (no changes in the sets of horizons) are included as subtypes into natural type classes (Fig. 4).

Fig. 4 Major elements of profile composition and taxonomic level of human-modified soils.

Traditional *soil names* were mostly retained in the new classification with two exceptions. First, components of soil names indicating environmental conditions (e.g., forest soils, meadow soils) were excluded. Second, new names were introduced for ‘new’ soils that were absent in the former system, for example, cryozems, rzhavozems. For plowed soils, the prefix ‘agro’ was proposed for the agrogenic soil types: agro-chnozem (PU-AU-BCA-Cca), agro-soddy-podzolic soil (P-EL-BEL-BT-C); for strongly eroded arable soils whose profiles comprise an arable horizon and subsoil, the name ‘agrozem’ is applied with the subsoil name, e.g., alfe-humus agrozem (P-BHF-C), dark-humus carbonate-accumulative agrozem (PU-BCA-Cca).

Theoretical aspects of soil classification were further developed by Ilia Sokolov. In 1978, he suggested the idea of a basic polycomponent soil classification that had much in common with Fridland’s (1982) proposal. Sokolov distinguished between stable (conservative) soil features reflecting the long history of soil development (soil memory) and dynamic soil characteristics reflecting current conditions of soil functioning (soil regimes) and argued in favor of their separate classification with further combination of these two components on a coordinate basis (Sokolov, 1978). Among stable features, it was proposed that the lithogenic heritage of soils derived from the parent material be classified separately from the pedogenic heritage. Another novelty introduced by Sokolov (1991) concerned the definition of the objects of classification. The entire universe of soils and soil-like bodies performing ecological functions of soils in the biosphere was embraced under a new term: Ecosols. At the highest level, Ecosols were subdivided into Natural, Natural-Artificial (anthropogenic), and Artificial kingdoms; each of them was classified in its own hierarchical system. The priority of the distinction between natural and artificial Ecosols was important in the context of the growing anthropogenic footprint in soils. A clear distinction was also made between soils (bodies shaped by pedogenesis from the already formed parent material) and pedoliths (bodies shaped by synchronous pedogenetic and geomorphic processes, such as aeolian, fluvial, or volcanic sedimentation; turbation; and hydrogenic accumulation of substances). Soils proper (normal soils of Dokuchaev) were separated at the fifth level of this system and further subdivided at four hierarchical levels. These two papers by Sokolov remained untranslated into English and had little impact on the development of soil classification ideas beyond Russia. Their theoretical significance has yet to be analyzed.

In the recent decade, key elements of Dokuchaev’s paradigm have been extended beyond the Earth to cover all loose surface formations (‘exons’) of lithospheric planets developing under the impact of exogenous factors. At the highest level, exons are subdivided into formations transported by lateral processes (‘transons’), in situ formations (‘sitons’), and transitional formations (‘transsitons’). In situ processes acting in sitons and transsitons result in differentiation of their vertical profiles. Such soil-like bodies have been named ‘soloids’ (Targulian et al., 2010, 2017). Soloids can be formed under the impact of cosmic, solar, lithospheric, atmospheric, hydrospheric, biospheric, and anthropospheric processes acting together or separately. This approach developed by Victor Targulian might be helpful in unveiling the history of Martian regolith and the search for Martian ‘soils’ (paleobiotic soloids). It can be considered ‘the revised edition’ of the agrogeological approach.

The search for better soil classification decisions continues throughout the world within Dokuchaev’s paradigm of soil science. It is now possible to analyze big soil and soil-related data. Will artificial intelligence confront or confirm Dokuchaev’s principles? How will they change? Pedologists are eager to know.

Conclusions

In concluding this brief overview on soil classifications created in the second half of the last century we may note that two aspects of Dokuchaev’s paradigm exerted a dual effect on soil classifications: (a) involving genesis as an open or concealed criterion for discriminating between classes of soils and (b) directly addressing soil-forming agents for aggregating soils into zonal entities. The WRB is an example of the first trend, and the USSR-1977 system of the second. The new Russian system has much in common with the WRB, which is being continuously updated: its new version has appeared in 2022.

Abstract

This chapter considers the characteristics of the two soil taxonomies that have made them world references: World Reference Base, WRB (IUSS Working Group WRB, 2015) and Soil Taxonomy, ST (Soil Survey Staff, 2014). Diagnostic horizons that serve to classify soils are mentioned, after recalling the genetic horizons. The first hierarchical levels of both taxonomies are described: the Reference Soil Groups of the WRB and the Orders of the Soil Taxonomy. Finally, the procedure for classifying and naming a soil is described using, as an example, the field observations and the analytical data from a soil profile of Toledo, Spain.

Key points

- Soils with similar properties have to have the same name.
- WRB and Soil Taxonomy as world reference systems.
- The basic rules for classifying soils are explained.

Introduction

This chapter introduces the use of the two reference soil taxonomies in the world: the World Reference Base, WRB (IUSS Working Group WRB, 2015) and Soil Taxonomy, ST (Soil Survey Staff, 2014). This chapter will be useful to soil scientists and those working in related and unrelated fields who struggle to understand how soil taxonomy works. Most users of soil information (from maps, reports or scientific articles), will probably never classify a soil themselves. But understanding the steps followed in the classification process may help to improve the interpretation of soils already classified. Classifying soils requires some knowledge of soil-forming processes and an ability to interpret the morphological description and the physical and chemical properties of the soils obtained from field and laboratory work (Arnold, 2005; Switoniak et al., 2018).

According to Soil Survey Staff (1999), a soil is defined as “A natural body comprised of solids (minerals and organic matter), liquid, and gases that occurs on the land surface, occupies space, and is characterized by one or both of the following: horizons, or layers, that are distinguishable from the initial material as a result of additions, losses, transfers, and transformations of energy and matter or the ability to support rooted plants in a natural environment”. For classification purposes, the lower depth limit of the soil in Soil Taxonomy is 2 m. Similarly, the object classified in the WRB is: “any material within 2 m of the Earth’s surface that is in contact with the atmosphere, excluding living organisms, areas with continuous ice not covered by other material, and water bodies deeper than 2 m” (IUSS Working Group WRB, 2015).

Why give names to soils? Classification lets us organize and transmit knowledge about our soils, making it possible to transfer the experience acquired in a given geographic area to other areas. This requires that soils with similar properties have the same name. Currently, the classification of soils is an essential instrument in research, and can be applied in many topics such as the rehabilitation of degraded areas, contaminated soils, land grabbing, (digital) mapping, and land evaluation and land assessments for different uses, such as vineyard zoning, irrigation projects of rainfed soils, etc. (Porta et al., 2003). In field research projects, it is usual to provide a description of the area of study: the geomorphology, the use of the land, the climate, the plant species, etc. In the same way, the name of the soil should be provided. As Kubiiena (1952) wrote: “For the rationalization of research in a natural science there is no other way than to rely on a systematic system as developed as possible. Can someone get any benefit from an experiment with plant material if the author cannot define exactly the name of the plant that he has used? Analogously, if the indications on the soil are missing, the total experiment remains in the air”.

Throughout the history of Soil Science, multiple national-based classification systems have been proposed and coexist, e.g., Australian, Brazilian, Canadian, Chinese, French, German, and others. But the two systems that are currently used as world references are: World Reference Base, WRB (IUSS Working Group WRB, 2015) and Soil Taxonomy (Soil Survey Staff, 2014).

Background of WRB and ST systems

Let us see how these most recent and current classifications (IUSS Working Group WRB, 2015; Soil Survey Staff, 2014) have been arrived at.

The International Society of Soil Sciences (ISSS) at its Sixth Congress, at Madison, Wisconsin (United States) in 1960 recommended that information about soils of the world should be compiled. The FAO-UNESCO (Food and Agriculture Organization of the United Nations), beginning in 1961, created a 1:5,000,000 soil map of the world (FAO, 1974), whose legend began to be used as if it were a true classification system. This legend was later revised (FAO, 1988) to be able to use it at more detailed scales and it would eventually become the current World Reference Base for soil resources (FAO-ISRIC-ISSS, 1998), which is successively updated (IUSS Working Group WRB, 2007, 2015). The WRB is intended to serve as a basis for correlation between existing classification systems, a communication tool for compiling global soil databases, and for the inventory and monitoring of the world's soil resources (Bridges et al., 1998; Deckers et al., 1998; Nachtergaele, 2005). The International Soil Reference and Information Centre (ISRIC) collects information on the world's soils and manages it with this taxonomy (<https://soilgrids.org>).

On the other hand, the Soil Taxonomy system developed from the need to order the several thousand series of soils recognized at the beginning of twentieth century (Brown, 2005). In 1951 the Soil Survey Staff (United States Department of Agriculture) began to work on a classification system that developed into many drafts or approximations. The Seventh Approximation, which was presented to the above mentioned Sixth Congress of the ISSS led to the official version of Soil Taxonomy edited in 1975 (Soil Survey Staff, 1975). Since then, several committees have periodically reviewed and added modifications that are reflected in the "Keys to Soil Taxonomy", whose first edition (Soil Survey Staff, 1983) has been successively improved until the latest version (Soil Survey Staff, 2014) and that the institution itself is updating (<https://www.nrcs.usda.gov>).

The 'Cornerstones' for classifying soils: Genetic and diagnostic horizons

Genetic horizons

The entry of matter and energy on the soil surface generates the formation of layers, whose upper and lower limits are often parallel to it and are known as soil horizons. The horizons are subdivisions of a soil into volumes considered to be homogeneous, which makes them the basic unit for describing and sampling a soil. Individual soils and their horizons are identified and described, in practice, by means of a soil profile, which may be seen, for example, in the exposed face of a soil pit or cutting. In fact, we can say that soil classification starts with differentiation of the horizons in the field and their complete and accurate description and sampling (FAO, 2006; Schoeneberger et al., 2012), later completed with analytical data.

The presence of these horizons results from the evolution or genesis of the soil from the parent material hence they are called genetic horizons, which applies to both the major classifications. These horizons are assigned by a combination of letters (uppercase and lowercase) and numbers, indicating the following:

1. The main horizons (or layers) are designated by a capital letter (master horizons), which informs about the position they occupy in the soil: A: top; B: middle; C: bottom.
2. The main process responsible for the formation of the horizon is indicated by lowercase letters that are added to the main horizon as a subscript or as a second character, i.e., Ap indicates that the surface horizon has been ploughed; Bt represents a subsurface horizon with a significantly higher percentage of phyllosilicate clay than the overlying soil material resulting from translocation (movement within the profile); Ck is a bottom horizon where secondary calcium carbonate has accumulated, etc.
3. With numerical indices the position of the horizon within the soil is designated, for example: Bt1, Bt2, etc.
4. Transition horizons are designated by the combination of letters of the relevant horizons, without indices. It differs between:
 - 4.1 no bar, if the properties of the horizon are intermediate although with a certain predominance of the characteristics of one horizon over those of the other, for example: AB or BA.
 - 4.2 with a bar, for example A/B, if the horizons are clearly identifiable, mixing one of them (A) with the other (B).
5. Lithic discontinuities are expressed by placing an Arabic numeral before the horizon letter, sequentially, for example: A-2C.

Although the use of this nomenclature is very similar in both the WRB and Soil Taxonomy, some differences remain, so the reader is redirected to the original sources.

Many master horizons and layers can have one or two (rarely three) lowercase letter suffixes, that must be cited according to some rules (FAO, 2006). The listing of genetic horizons ordered from the soil surface downwards is called a sequence. For example, Ap-Bt-Ck-C could be the sequence of an evolved profile of the Mediterranean region, whose details we will provide later.

Diagnostic horizons for mineral and organic soils

The description of genetic horizons is merely qualitative and is impractical for identifying and classifying soils, therefore, diagnostic horizons have been defined. They are defined morphometrically, with quantifiable physical and chemical properties measured in the field and laboratory, and usually related to soil-forming processes. Both WRB (IUSS Working Group WRB, 2015) and Soil Taxonomy (Soil Survey Staff, 2014) are based on diagnostic horizons, although they maintain some differences in their definition. In order to qualify for a particular soil grouping, a soil has to possess the measured criteria dictated in this definition.

Two types of diagnostic horizons are specified according to their positions in the soil profile: at the surface (surface horizons, named epipedons by the ST) and at depth below the surface (subsurface horizons). Between surface and subsurface horizons, 37 diagnostic horizons are currently defined by the WRB and 26 by the ST. Additionally, other diagnostic properties and materials are also used to classify soils, usually at a lower hierarchical level. Describing in detail the total requirements for diagnostic horizons, materials, and properties is beyond the scope of this chapter, so the reader is referred to original sources (IUSS Working Group WRB, 2015; Soil Survey Staff, 2014).

It is remarkable how Soil Taxonomy, unlike the WRB, uses climate as an important diagnostic characteristic for the classification of both mineral and organic soils, taking account of both the soil moisture and temperature regimes because of their strong influence on the soil formation processes (additions and losses of components, transformations and translocations within the profile). In this way, one soil order, specifically Aridisols, and most of the suborders are governed by soil moisture regimes, while soil temperature regimes become important at lower levels of Soil Taxonomy. Another example is the soil order Gelisols, which is based on soil features like permafrost that is strongly correlated with atmospheric climate. Climate features, however, are not considered in the soil definitions and classification by the WRB. The latter excludes climate for several reasons: to avoid subordinating soil classification to the availability of climate data and to avoid changes in the soil name by global or local climate change.

One of the most important differences between Soil Taxonomy and WRB systems focuses on the use or not of climate data

The characteristics that have allowed the WRB and the ST to be world reference soil classification systems are summarized below :

- The classification is based on soil characteristics defined in terms of diagnostic horizons, as well as properties and climate regime in ST and diagnostic properties and materials in WRB, which sustain relationships with soil-forming processes.
- They consider characteristics that, generally, are of significance for soil management.
- It can be applied objectively as it is based on quantified information.
- They have a hierarchical organization, modeled on biological taxonomy (Brown, 2005), in which different levels are defined with precision, so that it can be used at both a detailed and general level; Soil Taxonomy has six levels and WRB has two levels.
- Taxa are mutually exclusive.
- Once the nomenclature rules are understood, the terminology is clear and does not require translation into different languages and allows users to glean basic soil information from the name alone. The terminology used by ST is self-explanatory, whereas that of WRB retains names used traditionally.

The rules for classifying soils: How it works

In practice, the exposed soil pit (the profile) showing the horizons or layers serves as the basic unit for description and sampling in the field. The completed description of the profile and laboratory analytical data of each horizon, thereafter, allow classification.

To place a soil in its taxonomic class requires the use of the most recent version of the published Key (IUSS Working Group WRB, 2015; Soil Survey Staff, 2014). Users should be familiar with the meanings of the terms for describing the diagnostic criteria. The first step in classification consists of checking whether any of the genetic horizons or sub-horizons fulfill some of the criteria for diagnostic horizons, properties and materials. Once this is verified, the soil can be allocated first into the highest hierarchical level (Table 1) followed in subsequent steps to go down to the lower levels using the keys. All the keys in both taxonomies are designed in such a way that the user can determine the correct classification of a soil by going through them systematically.

(1) For the WRB classification, we need to identify diagnostic horizons and properties as well as diagnostic materials. Diagnostic horizons (anthraquic horizon, argic horizon, calcic horizon, etc.) and properties (abrupt textural difference, albeluvic glossae, andic properties, etc.) have a combination of attributes linked to processes of soil formation. Diagnostic materials are materials that influence pedogenetic processes or are indicative of them, i.e., albic material, artefacts, calcaric material, etc.

Detecting diagnostic elements (horizons, properties and materials) is the first step in allocating the soil into the appropriate Reference Soil Group (RSG), the first level of classification (Table 2). The user should go through the Key systematically, starting at the beginning and excluding all RSGs, one by one, for which the specified requirements are not met. The soil belongs to the first RSG for which it fulfils the criteria. The most extensive RSGs in the world are shown graphically in Fig. 1.

For the classification of a soil to the second level of the WRB, two types of qualifiers must be added to the name of the RSG:

- principal qualifiers, which are ranked and given in an order of importance, and
- supplementary qualifiers, which are simply arranged in alphabetical order.

Table 1 List of the first hierarchical levels of taxonomies: Reference Soil Groups (RSGs) of the WRB and the Orders of the Soil Taxonomy. The correlation between both is merely indicative.

Main characteristic	WRB (IUSS Working Group WRB, 2015)	STS (Soil Survey Staff, 2014)
1. Soils with thick organic layers	Histosols	Histosols
2. Soils with strong human influence		
With long and intensive agricultural use	Anthrosols	
Containing significant amounts of artefacts	Technosols	
3. Soils with limitations to plant growth		
Permafrost-affected	Cryosols	Gelisols
Arid climate	—	Aridisols
Thin or with many coarse fragments	Leptosols	(Entisols)
With a high content of exchangeable Na	Solonetzs	
High concentration of soluble salts	Solonchaks	
With shrink-swell clays	Vertisols	Vertisols
4. Soils distinguished by Fe/Al chemistry		
4.1 affected by groundwater or stagnating water		
Groundwater-affected, underwater and in tidal areas	Gleysols	
Stagnating water, structural difference and/or moderate textural difference	Stagnosols	
Stagnating water, abrupt textural difference	Planosol	
4.2 affected by Fe/Al chemistry		
Allophanes or Al-humus complexes	Andosols	Andisols
Subsoil accumulation of humus and/or oxides	Podzols	Spodosols
Accumulation and redistribution of Fe	Plinthosols	
Low-activity clay, P fixation, many Fe oxides, strongly structured	Nitisols	
Dominance of kaolinite and oxides	Ferralsols	Oxisols
5. Pronounced accumulation of organic matter in the mineral topsoil		
Very dark topsoil, secondary carbonates	Chernozems	Mollisols
Dark topsoil, secondary carbonates	Kastanozems	
Dark topsoil, no secondary carbonates, high base status	Phaeozems	
Dark topsoil, low base status	Umbrisols	
6. Accumulation of substances		
Accumulation of, and cementation by, secondary silica	Durisols	(Inceptisols)
Accumulation of secondary gypsum	Gypsisols	
Accumulation of secondary carbonates	Calcisols	
7. Soils with clay-enriched subsoil		
Interfingering of coarser-textured, lighter colored material into a finer-textured, stronger colored layer	Retisols	Ultisols, Alfisols
Low-activity clays, low base status	Acrisols	
Low-activity clays, high base status	Lixisols	
High-activity clays, low base status	Alisols	
High-activity clays, high base status:	Luvissols	
8. Soils with little or no profile differentiation		
Moderately developed	Cambisols	Inceptisols
Sandy	Arenosols	Entisols
Stratified fluvatile, marine and lacustrine sediments	Fluvisols	
No significant profile development	Regosols	

Note: this table is not to be used as a key. For full definitions, please refer to original sources (IUSS Working Group WRB, 2015; Soil Survey Staff, 2014).

Unlike ST, in the WRB there are no additional keys to qualify for the second level. Both types of qualifiers are listed in the key for each of the RSGs (IUSS Working Group WRB, 2015). The principal qualifiers are added before the name of the RSG without brackets and without commas and sequenced from right to left. The supplementary qualifiers are added in brackets after the name of the RSG, separated by commas. Both qualifiers types must start with capital letters. This soil, whose steps for its classification we will develop at the end of this chapter, can serve as an example:

The RSGs are related to the primary processes that condition soil formation while the second level qualifiers focus on specific physical and chemical properties of the soil, usually with a significant effect on land use.

Table 2 RSG formative elements and main characteristics.

RSG	Formative element	Connotation
Acrisols	From Latin <i>acer</i> , very acid	Strongly weathered acid soils with low base saturation and argic with low-activity clays
Alisols	From Latin <i>alumen</i> , alum	Strongly weathered acid soils with low base saturation and argic with high-activity clays
Andosols	From Japanese <i>an</i> , dark, and <i>do</i> , soil.	Dark soils developed on glass-rich volcanic material (andic or vitric properties)
Anthrosols	From Greek <i>anthropos</i> , human being.	Soils modified by long-continued cultivation or addition of material (anthropogenic diagnostic horizons).
Arenosols	From Latin <i>arena</i> , sand	Sandy soil, with a textural class of loamy sand or coarser (and no skeletal)
Calcisols	From Latin <i>calx</i> , lime	With substantial accumulation of secondary lime (calcic or petrocalcic horizon)
Cambisols	from Late Latin <i>cambiare</i> , to change.	soils with at least an incipient subsurface soil formation (cambic horizon)
Chernozem	From Russian <i>cherniy</i> , black, and <i>zemlya</i> , earth or land	Blackish humus-rich surface horizon (chernic) with accumulation of secondary carbonates with depth (protocalcic properties or calcic horizon)
Cryosols	From Greek <i>kryos</i> , cold	Frost-affected soils
Durisols	from Latin <i>durus</i> , hard	Soils with hardened secondary silica
Ferralsols	From Latin <i>ferrum</i> , iron, and <i>alumen</i> , alum	Red and yellow tropical soils with a high content of sesquioxides
Fluvisols	From Latin <i>fluvius</i> , river	Soils developed in recent fluvial deposits (fluvic material)
Gleysols	From Russian <i>gley</i> , mucky mass	Soils with clear signs of groundwater influence (gleyic properties)
Gypsisols	From Greek <i>gypsos</i> , gypsum	Soils with substantial accumulation of secondary gypsum (gypsic or petrogypsic horizon)
Histosols	From Greek <i>histos</i> , tissue	Peat and muck soils (with histic horizon)
Kastanozems	From Latin <i>castanea</i> and Russian <i>kashtan</i> , chestnut, and Russian <i>zemlya</i> , earth or land	Dark brown, humus-rich surface horizon (mollic) with accumulation of secondary carbonates with depth (protocalcic properties or calcic horizon)
Leptosols	From Greek <i>leptos</i> , thin	Thin soils with no diagnostic horizons
Lixisols	From Latin <i>lixivia</i> , washed-out substances	soils with high base saturation and argic with low-activity clays
Luvisols	From Latin <i>eluere</i> , to wash	soils with high base saturation and argic with high-activity clays
Nitisols	From Latin <i>nitidus</i> , shiny	red tropical soils with a clayey (nitic) horizon shiny aggregate faces
Phaeozems	From Greek <i>phaios</i> , dusky, and Russian <i>zemlya</i> , earth or land	Dark brown, humus-rich surface horizon (mollic) without accumulation of secondary carbonates with depth
Planosols	From Latin <i>planus</i> , flat	With a coarse-textured surface horizon abruptly over a dense and finer textured subsoil (abrupt textural difference), typically in seasonally waterlogged flat lands
Plinthosols	From Greek <i>plinthos</i> , brick	Soils with plinthite, petroplinthite or pisoliths; that is with plinthic, petroplinthic or pisoplinthic horizons
Podzols	From Russian <i>pod</i> , underneath, and <i>zola</i> , ash	Soils with an eluvial horizon (albic material), which has the appearance of ash on an illuvial spodic horizon
Regosols	From Greek <i>rhegos</i> , blanket	Weakly developed soils in unconsolidated material with no diagnostic horizons
Retisols	From Latin <i>rete</i> , net	Clay illuviation horizon (argic) with retic properties, that is an interfingering of coarser-textured albic material into the illuviation horizon forming a net-like pattern
Solonchaks	From Russian <i>sol</i> , salt and <i>chak</i> , salt-affected area	Saline soils (salic horizon)
Stagnosols	From Latin <i>stagnare</i> , to flood	With perched water (stagnic properties)
Solonetz	From Russian <i>sol</i> , salt and <i>etz</i> , extremely	Soils with a high content of exchangeable Na (natric horizon)
Technosols	From Greek <i>technikos</i> , skilfully made	Artificial soil, with artefacts or technic hard material, built by the human activity
Umbrisols	From Latin <i>umbra</i> , shade	With dark brown umbric surface horizon
Vertisols	From Latin <i>vertere</i> , to turn	Heavy clay soils with a high proportion of swelling clays (vertic horizon)

Additionally, qualifiers that have depth requirements may be combined with specifiers (Epi-, Endo-, Amphi-, Ano-, Kato-, Panto-, Bathy-, etc.) to create subqualifiers (e.g., Epicalcic), showing the depth (or intensity) to which the property is occurring.

(2) In Soil Taxonomy, the highest hierarchical level are the Orders (12), see Table 3, followed by Suborders (64), Great groups (>300), Subgroups (>2400), Family and Series. The first four levels are primarily governed by climate and soil genesis, with the family and series levels capturing important physical and chemical properties for crop growth, engineering, and land management (Brown, 2005). To classify soils down to the Subgroup level, the following diagnostic criteria are required: materials (organic and mineral), horizons and diagnostic characteristics, and climate (moisture and temperature regime). To classify at the family level, it is additionally required to identify classes of: particle size, mineralogical constituents, soil depth, consistency, coatings and cracks. Series name of the soil is usually designated by the local name of the site where it is dominant, or where it was described for the first time.

Once we have identified which diagnostic criteria fulfill the horizons and layers of our soil, the next step consists of assigning the soil to the first hierarchical level: the Order (Table 2). The user must start at the beginning of the “Key to Soil Orders” and eliminate, one by one, all classes that include criteria that do not fit the soil in question. Soils are keyed out in order, starting with Gelisols and ending with Entisols. The soil belongs to the first class listed for which it meets all the required criteria. Once the Order has been assigned, the next step will be the “Key to Suborders” and so the process is repeated until the subgroup level is reached.

Below some representative soil profiles of various orders of Soil Taxonomy and their RSG equivalents (WRB) are shown (Fig. 2).

Fig. 1 Land surface (%) occupied by the main RSGs. From FAO (2001) Lecture Notes on the Major Soils of the World (With CD-ROM), by P Driessen, JA Deckers, O Spaargaren and F Nachtergaele (eds). *World Soil Resources Report No. 94*. pp. 334, Rome: FAO.

Table 3 Formative elements in the Orders of ST and main characteristics.

Orders	Formative element & origin	Connotation
Alfisols	Alf, from Pedalfer (Marbut classes)	No acid soils with an argillic, natric or kandic subsurface diagnostic horizon
Andisols	And, From Japanese <i>an</i> , dark, and <i>do</i> , soil.	Dark soils developed on glass-rich volcanic material (andic properties)
Aridisols	Id, from Latin <i>aridus</i> , dry	Soils with aridic moisture regime
Entisols	Ent, from English <i>recent</i> ,	Young soils: with ochric epipedon and no subsurface diagnostic horizon
Gelisols	El, from Latin <i>gelu</i> , ice	Soils that have permafrost or gelic materials
Histosols	Ist, from Greek <i>histos</i> , (plant) tissue	soils organic soil materials saturated with water for 30 days or more per year (peatbog)
Inceptisols	Ept, from Latin <i>inceptum</i> incipient	Soil with an incipient weathering revealed with some diagnostic horizon as cambic, calcic, gypsic, etc., without aridic moisture regime
Mollisols	Oll from Latin <i>mollis</i> , soft	With epipedon mollic with a base saturation of 50% or more throughout
Oxisols	Ox from French <i>oxide</i>	Strongly weathered acid soils with an oxic horizon
Spodosols	Od, from Greek <i>spodos</i> , ash	Soils with an illuvial spodic horizon, usually underling an eluvial albic horizon (<i>L. albus</i> , white)
Ultisols	Ult, from Latin <i>ultimus</i> , latest	Very acid soils with an argillic, kandic or fragipan subsurface diagnostic horizons and very low base saturation (BS <35%)
Vertisols	Ert, from Latin <i>vertere</i> , to turn.	Heavy clay soils with slickensides or other vertic characteristics, such as wedge-shaped peds and surface cracks, that open and close periodically, due to the high proportion of swelling clays

Fig. 2 Some of the most common soil morphologies showing their genetic horizons. The RSG (WRB) and most probable order (ST) is indicated.

In Fig. 2 starting at the left there are soil profiles of less development (with simple sequences of horizons A-R or A-C) and towards the right profiles of greater development (A-E-B-C); there is a gradient of processes ranging from incipient weathering and melanization to gypsification, calcification, argilluviation and podzolization. To a greater or lesser degree, these processes and its resulting properties are incorporated into the denomination of these soils.

Example profile

The site description, and essential field description and analytical properties data for a profile in the center of Spain are provided in Table 4. Using this information, the key diagnostic horizons are outlined. This example shows that the depths of the horizons described in the field do not always coincide with the depths required for the diagnostic horizons. The top 18 cm (Ap1 and top Ap2) fulfill the requirements for an ochric horizon (STS). The thick Bt-horizon described in the field meets the requirement for an illuvial horizon (observed clay coatings) and increase in phyllosilicate clay for an argillic/argic horizon (STS/WRB, respectively). It should be noted that the increase requested by both taxonomy systems is different ($\times 1.2$ STS and $\times 1.4$ WRB), which is not uncommon for other criteria in other diagnostic horizons and properties. The Ck horizon has the overall quantity of CaCO_3 equivalent required (15% or more, by weight, in the fine-earth fraction) and much evidence of its illuviation: its CaCO_3 equivalent is 5% or more (absolute) higher than that of the underlying C-horizon; moreover, 5% or more (by volume) are identifiable secondary carbonates.

Table 4 La Higuera Soil Profile: Calcic Haploxeralf (Soil Survey Staff, 2014), Calcic Chromic Luvisol (Loamic, Aric, Cutanic, Hypereutric, Ochric).

Site description										
Location: Experimental farm "La Higuera" (CSIC), Toledo, Spain						Stoniness: no stones on the surface or within the profile				
Altitude: 460 m above sea level						Moisture regime: Xeric				
Landform: Plain (1% slope), East facing						Temperature regime: Thermic				
Parent material: Arkosic sandstones and clays (Miocene)						Drainage: Moderately well drained				
Land use: rainfed winter cereals						Clay minerals in Bt horizon: Illites, smectites and kaolinites				

	Sand %	Silt %	Clay %	EC 1:5 dS/m	CaCO_3 eq %	Base saturation %	pH 1:2.5	Org C %	CEC $\text{cmol} + \text{kg}^{-1}$	CEC/clay $\text{cmol} + \text{kg}^{-1}$
Horizon										
Ap1 (0–10 cm)	76	5	19	0.2	0	47	5.9	0.8	11	58
Ap2 (10–36 cm)	69	9	22	0.1	0	53	6.6	0.3	15	68
Bt (36–78 cm)	50	12	39	0.3	0	61	7.5	0.3	36	92
Ck (78–108 cm)	37	25	36	0.1	19	100	7.8	0.1	41	120
C (>108 cm)	41	21	38	0.1	11	100	7.9	0.1	30	80
	10YR 6/4 (dry) and 10YR 5/4 (wet), clay loam, massive structure, few (<5% v/v) soft accumulations of secondary carbonates									

		DIAGNOSTIC HORIZONS			
		STS:	OCHRIC	ARGILLIC	CALCIC
	Genetic horizons	WRB:	None	ARGIC	CALCIC
	Ap1 0–10 cm		(18 cm) Value w = 4.5>3 Value dry= 6 > 5 Org C=0.5%<0.6 % (w/w) cutoff	Elluvial horizons 22 x 1.2=26.4 % cla ST cutoff 22 x 1.4=30.8 % clay WRB cutoff	CaCO ₃ None
	Ap2 (10–36 cm)				
Bt (36–78 cm)		39% clay >> ST and WRB cutoff Common (10% v/v) clay coatings Not natric	CaCO ₃ None		
Ck 78–108 cm			CaCO ₃ =19% (w/w) > 15% cutoff Second. CaCO ₃ 20% (v/v) > 5 % cutoff		
C >108 cm			CaCO ₃ =11% w/w		

These diagnostic horizons, related to processes of formation, will be essential to classify soils at the first hierarchical levels of both taxonomies. For the WRB key, with the diagnostic horizons obtained (an argic not permeated with secondary carbonates above a calcic one) we can place the soil profile at the first level within the Luvisol Reference Soil Group. To classify to the second level of the system (IUSS Working Group WRB, 2015) it is necessary to use not only diagnostic horizons but also diagnostic properties and diagnostic materials. We need to check if the soil conforms to the definitions given to be used as principal and supplementary qualifiers. Reviewing the lists of the principal qualifiers, we can choose the following:

- Chromic (by the reddish color of a subsurface horizon), and
- Calcic (by the presence of the “calcic” diagnostic horizon)

Between the supplementary qualifiers, we can choose:

- Loamic (by the loamy texture),
- Aric (being ploughed to a depth of ≥ 20 cm from the soil surface),
- Cutanic (by the abundance of clay coatings),
- Hypereutric (by the relatively high base saturation between 20 and 100 cm) and.
- Ochric (by the moderate organic C content in the surface horizon, Ap).

Therefore, the profile used here as an example is classified as a Chromic Calcic Luvisol (Loamic, Aric, Cutanic, Hypereutric, Ochric) at the second level of the WRB system (IUSS Working Group WRB, 2015). Note that, the principal qualifiers are added before the name of the RSG without brackets and without commas. The sequence is from right to left, i.e., the lowermost qualifier in the list (here Calcic) is placed closest to the name of the RSG. The supplementary qualifiers are added in brackets after the name of the RSG always placed in the order of the alphabet and separated from each other by commas.

To classify this soil by ST (Soil Survey Staff, 2014), we also need to know the horizons and diagnostic characteristics but, moreover, we need to have some climate data, even for the higher categories, especially the soil moisture regime. In the profile taken as an example in this section, we have: a surface diagnostic horizon or epipedon (ochric), and two subsurface diagnostic horizons (argillic and calcic) with a xeric soil moisture regime, which allows us to classify the soil as Calcic Haploxeralf, at subgroup level (Soil Survey Staff, 2014). Pay attention to the fact that this nomenclature picks up the hierarchical structure of the system. Soil names in Soil Taxonomy are formulated from right to left, with formative elements (segments or syllables) drawn from the diagnostic horizons previously listed. This nomenclature system can be illustrated for this Calcic Haploxeralf:

<i>Hierarchical level</i>	<i>Order</i>	<i>Suborder</i>	<i>Great Group</i>	<i>Subgroup</i>
Name	Alfisol	Xeralf	Haploxeralf	Calcic Haploxeralf
Formative elements	Alf + i + sol	Xer + alf	Haplo + xeralf	Qualifier + Group
<i>Segment or syllable</i>	<i>Calcic</i>	<i>Haplo +</i>	<i>xer +</i>	<i>alf</i>
Hierarchical level	Subgroup	Great group	Subgroup	Order

Summary

This chapter highlights how to classify soils according to their properties, which are generally related to soil formation and management, following the world benchmarks: the WRB and Soil Taxonomy systems. These classifications are dynamic, and change over time to the extent that our knowledge about the soil does. Naming the soil synthesizes all this knowledge through a few qualifiers. On the contrary, interpreting the name of a soil requires being able to identify its components, properties and capabilities for different uses (agricultural, pastoral, forestry, etc.). For as long as we continue to cultivate the land, to carry out scientific experiments on the soils and to transfer the knowledge obtained in them, the classification of soils will be required.

Abstract

The World Reference Base (WRB) is an international soil classification system that evolved from the FAO–UNESCO Legend of the Soil Map of the World. It is intended to name both natural and human-made soils within the first two meters of the Earth’s terrestrial surface. Soils are classified by diagnostic features, as in all modern classification systems. The WRB uses two hierarchical levels only: 32 Reference Soil Groups (RSGs) at the first level and an undetermined number at the second level as soils are named by combining the RSG with qualifiers. The WRB is continuously being tested and updated, with the latest edition presented in 2022 at the 22nd World Congress of Soil Science in Glasgow.

Key points

- WRB evolved from the FAO-UNESCO Legend of the Soil Map of the World
- WRB allows naming any part of the upper 2 m from the terrestrial Earth’s surface and facilitates correlation between national classification systems
- Soils are classified based on diagnostic features (horizons, properties, and materials)
- WRB has only two hierarchical levels of classification with 32 Reference Soil Groups (RSGs) at the highest level
- At the second level, soils are named by adding qualifiers to the RSG; the qualifiers are selected from lists making it a flexible and open system.
- How WRB correlates with Soil Taxonomy is explained
- Examples of applications from WRB are presented

Historical background

The international soil classification system, the World Reference Base for Soil Resources (WRB), evolved from the FAO-UNESCO legend of the Soil Map of the World (FAO, 1988; FAO-UNESCO, 1971). The FAO–UNESCO soil maps were published in the 1970s–1980s. After the Second World War, out of concern to meet world food demands, many countries invested in the survey of soils in support of the agricultural sector. With the lack of an international soil classification system, individual countries elaborated upon national soil survey protocols and classification systems which hampered global or even regional comparisons.

In 1960, the Seventh Congress of the International Soil Science Society (ISSS, now the International Union of Soil Sciences – IUSS) in Madison, Wisconsin, USA, recommended that soil maps of large regions and continents should be produced. The FAO and UNESCO decided to create a Soil Map of the World in 1961. It took worldwide collaboration between innumerable soil scientists to produce the maps over about 20 years, and this was the first global inventory of natural resources at a scale as detailed as 1:5 million (FAO–UNESCO, 1974). The ISSS recommendations for the Soil Map of the World project were substantiated with six

objectives (FAO, 1988; Nachtergaele, 2005): to (i) make a first appraisal of the world's soil resources; (ii) supply a scientific base for the transfer of experience between areas with similar environments; (iii) promote the establishment of a generally accepted soil classification system and nomenclature; (iv) establish a common framework for more detailed investigations in developing areas; (v) prepare a document for educational, research, and development activities, and (vi) strengthen international contacts in the field of soil science. The third objective, promotion of a nomenclature and soil classification system that is widely accepted, aligns with the WRB's evolution into an international classification system.

Development of the WRB

As a first step toward the creation of a global soil classification system, an international group of soil scientists launched the "International Reference Base for Soil Classification" project in 1980. The project was endorsed by the ISSS in 1982 and the International Reference Base for Soil Classification (IRB) working group was established within Commission V of the ISSS. In 1992, the IRB was renamed to World Reference Base for Soil Resources (WRB), and its working group was created at the Fifteenth World Congress of Soil Science in Acapulco in 1994.

The prime objective of the working group was to provide scientific depth and background to the Revised FAO Legend and to ensure that the latest knowledge relating to global soil resources and interrelationships was incorporated in a world-wide soil reference system (Spaargaren and Deckers, 1998). The first edition of the WRB (ISSS-ISRIC-FAO, 1998) together with explanatory texts (ISSS Working Group RB, 1998a, b) were presented at the Sixteenth World Congress of Soil Science in Montpellier, France. The great interest in the WRB transpires from the fact that it was translated into 15 languages. Furthermore, the Lecture Notes on the Major Soils of the World (Driessen et al., 2001), based on the WRB, were widely used. A second edition of the WRB was published in 2006, with an update in 2007 (IUSS Working Group WRB, 2007), a third update in 2014, and one in 2015 (IUSS Working Group WRB, 2015). At the World Congress of Soil Science in Glasgow, July–August 2022, the fourth edition was presented (IUSS Working Group WRB, 2022).

The WRB has grown beyond a system for correlation between national classification systems. The European Union adopted WRB for soil maps and for land information databases and also published a Soil Atlas of Europe based on it (Jones et al., 2005). Several countries use the WRB as a soil classification system and for mapping, or for updating their legacy soil survey data as, for example, in Belgium (Dondeyne et al., 2014), Hungary (Dobos et al., 2019) and Nepal (Lamichhane et al., 2021).

The WRB working group is part of the IUSS Division 1 (Soils in Space and Time) and falls under Commission 1.4. (Soil Classification). It consists of an international group of soil scientists testing, revising, and improving WRB as an academic service to society. Comments and suggestions from those applying WRB are greatly appreciated and field excursions are organized annually to test the system further. These excursions provide the basis for reviewing and revising the rules and definitions and are essential for updating and improving the system.

Structure

At the highest level of classification the WRB has 32 Reference Soil Groups (RSGs) which are identified through a key. The RSGs group soils that share dominant soil forming processes and which are convenient for making generalized global soil maps (Fig. 1). At the second level, soil names are constructed by adding qualifiers to the RSGs. The qualifiers represent morphologic, physical, or chemical characteristics that strongly affect the soil's functioning. Some qualifiers are specific to a few or even just one RSG while other qualifiers are foreseen to be combined with various RSGs.

The reference soil groups

The basic philosophy of the WRB is that Reference Soil Groups must represent a minimal geographical coverage and reflect some dominant soil-forming processes (Spaargaren and Deckers, 1998). In Table 1, the RSGs are aggregated into nine sets according to dominant soil forming processes and identifiers. Striking characteristics, and limitations relevant for land husbandry are also indicated for each RSG.

The qualifiers

What sets WRB apart from other soil classification systems is that at the second, most detailed, level soils are named according to a flexible, open system. In the current (4th) edition of WRB (IUSS Working Group WRB, 2022) 281 qualifiers have been defined for naming soils at the second level. Soils are differentiated according to features resulting from secondary soil-forming processes that have altered the primary characteristics and that affect land-uses, or, more generally, soil functions. Some qualifiers are specific to one or only a few RSGs while others can be combined with many RSGs. The qualifiers are divided into principal and supplementary qualifiers. Principal qualifiers are regarded as the most pertinent in relation to soil functioning and are ranked according to their perceived importance. Supplementary qualifiers provide additional details about the RSG. They are not ranked but listed in alphabetical order (except for the supplementary qualifiers pertaining to the texture which are given first). Many qualifiers are mutually exclusive, and, in practice, most classified soils have fewer than 10 qualifiers. When a soil is classified for which a qualifier would apply that is not foreseen in the list, it can still be added as a supplementary qualifier. In this way the classification system is flexible and open.

Fig. 1 The Reference Soil Groups represent soils that share some dominant soil forming processes and which are convenient for making generalized global soil maps [authors' mapped based on the Harmonized Soil Map of the World (FAO-IIASA-ISRIC-ISSACS-JRC, 2012)].

The diagnostics

The classification of soils in the WRB is based on soil features defined as diagnostic horizons (Table 2), diagnostic properties, and diagnostic materials (Table 3), together called the diagnostics. The WRB diagnostics require a minimum expression of one or more characteristics (or a combination of them), occurring within a specified depth. These characteristics are assessed in the field or may require laboratory analyses.

A diagnostic horizon is a soil layer, with distinct properties, or consisting of particular materials with a minimum thickness. A vertic horizon, for example, must have at least 30% clay, and must have at least 20% by volume of wedge-shaped soil aggregates or slickensides on more than 10% of the surfaces of soil aggregates, and must have shrink-swell cracks, and must have a thickness of 25 cm or more. Typical slickensides, wedge-shaped aggregates, and shrink-swell cracks of a Vertisol are shown in Fig. 2.

Diagnostic properties reflect soil-forming processes, or soil-forming conditions, but are not defined by the thickness of the particular layer. Diagnostic materials describe the nature of the soil material, without referring to the parent material. Table 3 presents the diagnostic properties and materials of the WRB.

Diagnostic properties can be observed or measured in the field or laboratory and require a minimum or maximum expression to qualify as diagnostic. Diagnostic materials significantly influence soil-forming processes. Their characteristics refer (as for all diagnostics) to the fine earth fraction (<2 mm), unless stated otherwise. Table 3 presents the diagnostic properties and materials of the WRB.

Within a soil profile a layer may have overlapped or diagnostics that coincide as illustrated by the soil profile in Fig. 3. The surface horizon (0–45 cm) is relatively thick (>20 cm), dark-colored and well structured, and has a large content of organic matter ($\geq 0.6\%$) and a high base saturation ($\geq 50\%$), as revealed by laboratory analyses. It therefore fulfills the criteria of a Mollic horizon. As the profile is developed in volcanic material, it contains volcanic glass, so it has vitric properties, and because it contains short-range-order minerals, it also has andic properties.

Naming soils

In naming a soil in the WRB the first step is to specify the diagnostics. These are identified by checking all the diagnostic criteria. A complete soil profile description is required to detect the diagnostics for a soil. To ensure that the recorded observations and data

Table 1 Reference Soil Groups aggregated according to dominant identifier and striking properties representing potentials and constraints for land husbandry. Note this sequence does not follow the key exactly. For the exact definition of the RSGs see (IUSS Working Group WRB, 2022).

Set	RSGs (code)	Dominant identifier and properties
1	Accumulation of organic matter	
	Histosols (HS)	Soils with very large organic matter contents that are water saturated or occur in areas with very high precipitation. Important for C sequestration, and biodiversity, and highly susceptible to subsidence and resulting into large emissions of CO ₂ and CH ₄ when drained
2	Mineral soils strongly influenced by human actions	
	Anthrosols (AT)	Ancient agricultural land; often important for C sequestration
	Technosols (TC)	Large amounts of artifacts; soil sealing, potentially high levels of contaminants and pollutants
3	Shallow and weakly developed mineral soils	
	Cryosols (CR)	Permafrost affected soils; important for C sequestration but with strong potential of CO ₂ and CH ₄ emission
	Leptosols (LP)	Rocky areas, or thin soils with many coarse fragments with usually very limited potential for agricultural production but valuable for nature conservation or forestry
	Regosols (RG)	Soils with no discernible profile development, of very varying potential for land-use and conservation
	Cambisols (CM)	Soils with the beginning of soil development, of very varying potential for land husbandry
4	Mineral soils with impeded drainage or formed from river, lake or sea deposits	
	Gleysols (GL)	Soils with shallow groundwater, mostly of good chemical fertility
	Planosols (PL)	Seasonally water saturated soils with lighter textured topsoil over heavy textured subsoil. Limited by poor drainage
	Stagnosols (ST)	Soils affected by seasonal stagnation of surface water but without strong textural differentiation. Limited by poor drainage
	Fluvisols (FL)	Soils formed from recent river, lake or marine deposits, subject to regular flooding but generally of high chemical fertility
5	Mineral soils strongly influenced by parent material	
	Andosols (AN)	Soils formed in volcanic materials, with mostly good chemical fertility but highly susceptible to soil erosion
	Vertisols (VR)	Soils with shrink-swell clay minerals of alternating wet and dry conditions, with mostly good chemical fertility but highly susceptible to gully erosion
	Arenosols (AR)	Soils of residual and shifting sands, with limited or no soil profile development, with mostly low chemical fertility and low water holding capacity
6	Mineral soils with high levels of Fe and Al oxides	
	Podzols (PZ)	Soils with accumulation of humus and or Fe–Al oxides in the subsoil. Soils with low fertility and strong acidity
	Plinthosols (PT)	Soils marked by the presence of iron-rich clayey material (plinthite) that hardens irreversibly upon drying, or that has hardened into ironstone (petroplinthite). Limited by drainage, stoniness or soil depth
	Nitisols (NT)	Deep, well-drained, reddish or yellowish soils with more than 30% clay with characteristic shiny, blocky or polyhedral structural elements. Good infiltration capacity, but susceptible to landslides
	Ferralsols (FR)	Deeply weathered reddish or yellowish soils with high content of Fe and Al oxides, and very low cation exchange capacity. Soils of low chemical fertility but often with good structural properties
7	Mineral soils with pronounced accumulation of organic matter in the topsoil	
	Chernozems	Soils with very dark organic matter rich topsoil and with secondary carbonates; soils with good infiltration capacity and highly fertile
	Kastanozems	Soils with brownish organic matter rich topsoil and with secondary carbonates; soils with good infiltration capacity and highly fertile
	Phaeozems	Soils with dark or brownish organic matter rich topsoil, without secondary carbonates, but with high base status and highly fertile
	Umbrisols	Soils with dark or brownish organic matter rich topsoil, with low base status (acidic soils)
8	Mineral soils with accumulation of salts, and non-saline secondary minerals	
	Solonchaks (SC)	Soils with high content of soluble salts in the topsoil. Very restricted plant growth, and highly susceptible to water and wind erosion
	Solonetz (SN)	Soils with high content of Na in the clay-enriched subsoil. Limited water infiltration capacity and susceptible to slaking and water erosion. High Na content is harmful to many plants
	Durisols (DU)	Soils with accumulation and cementation of secondary silica. Free draining soils mostly limited by shallow soil depth
	Gypsisols (GY)	Soils with accumulation of secondary gypsum. Limited by plant nutrient imbalance, soil depth, and stoniness
	Calcisols (CL)	Soils with accumulation of secondary carbonates. Can be highly productive, particularly under irrigation but can be constrained by limited soil depth and risk for salinization
9	Mineral soils with accumulation of clay in the subsoil	
	Retisols (RT)	Soils with a clay-enriched subsoil horizon that is interfingering by coarser-textured, lighter colored material. Can be limited by water infiltration capacity
	Acrisols (AC)	Soils with a clay-enriched subsoil horizon of low-activity clays and with low base status. Soils limited by low chemical fertility
	Lixisols (LX)	Soils with a clay-enriched subsoil horizon of low-activity clays and with high base status. Soils with relatively high chemical fertility
	Alisols (AL)	Soils with a clay-enriched subsoil horizon of high-activity clays and with low base status. Soils limited by high acidity
	Luvissols (LV)	Soils with a clay-enriched subsoil horizon of high-activity clays and with high base status. Soils with high chemical fertility

Authors' synthesis based on (Driessen et al., 2001; IUSS Working Group WRB, 2022).

Table 2 Descriptive overview of diagnostic horizons^a.

<i>Diagnostic horizons</i>	
<i>Name</i>	<i>Simplified Description</i>
1. Anthropogenic diagnostic horizons (all are mineral)	
Anthraquic horizon	In paddy soils: the layer comprising the puddled layer and the plow pan, both showing a reduced matrix and oxidized root channels
Hortic horizon	Dark, large content of organic matter and P, high animal activity, high base saturation; resulting from long-term cultivation, fertilization and application of organic residues
Hydragric horizon	In paddy soils: the layer below the anthraquic horizon showing redoximorphic features and or an accumulation of Fe and or Mn
Irragic horizon	Uniformly textured, at least moderate content of organic matter, high animal activity; gradually built up by sediment-rich irrigation water
Plaggic horizon	Dark, at least moderate content of organic matter, sandy or loamy; resulting from application of sods and excrements
Pretic horizon	Dark, at least moderate content of organic matter and P, large contents of exchangeable Ca and Mg, with black carbon; including Amazonian Dark Earths (also known as <i>Terra Preta</i>)
Terric horizon	Evidence of addition of substantially different material, at least moderate content of organic matter, high base saturation; resulting from adding mineral material (with or without organic residues) and cultivation
2. Diagnostic horizons that may be organic and or mineral	
Calcic horizon	Accumulation of secondary carbonates, not continuously cemented
Cryic horizon	Perennially frozen (visible ice or, if not enough water, < 0 °C)
Salic horizon	Large amounts of readily soluble salts
Thionic horizon	With sulfuric acid and a very low pH
3. Organic diagnostic horizons	
Folic horizon	Organic layer, not water-saturated and not drained
Histic horizon	Organic layer, water-saturated or drained
4. Surface mineral diagnostic horizons	
Chernic horizon	Thick, very dark-colored, high base saturation, moderate to high content of organic matter, well developed soil structure or structural elements created by cultivation, high biological activity (special case of the mollic horizon)
Mollic horizon	Thick, dark-colored, high base saturation, moderate to high content of organic matter, at least some soil structure or structural elements created by cultivation
Umbric horizon	Thick, dark-colored, low base saturation, moderate to high content of organic matter, at least some soil structure or structural elements created by cultivation
5. Other mineral diagnostic horizons related to the accumulation of substances due to (vertical or lateral) migration processes	
Argic horizon	Subsurface layer with distinctly higher clay content than the overlying layer without a lithic discontinuity and or presence of illuvial clay minerals (with or without a lithic discontinuity)
Duric horizon	Concretions or nodules, cemented by secondary silica, and/or fragments of a broken-up petroduric horizon
Ferric horizon	≥ 5% reddish to blackish concretions and or nodules or ≥ 15% reddish to blackish coarse masses, with accumulations of Fe (and Mn) oxides
Gypsic horizon	Accumulation of secondary gypsum, not continuously cemented
Limonic horizon	Accumulation of Fe and or Mn oxides in a layer that has or had gleyic properties; at least partially cemented
Natric horizon	Subsurface layer with distinctly higher clay content than the overlying layer without a lithic discontinuity and or presence of illuviated clay minerals; high content of exchangeable Na
Petrocalcic horizon	Accumulation of secondary carbonates, relatively continuously cemented
Petroduric horizon	Accumulation of secondary silica, relatively continuously cemented
Petrogypsic horizon	Accumulation of secondary gypsum, relatively continuous cemented
Petroplinthic horizon	Consists of oximorphic features inside (former) aggregates that are at least partially interconnected and have a yellowish, reddish and or blackish color; large contents of Fe oxides at least in the oximorphic features; relatively continuously cemented
Pisoplinthic horizon	≥ 40% at least moderately cemented yellowish, reddish, and or blackish concretions and/or nodules, with accumulation of Fe oxides
Plinthic horizon	Has in ≥ 15% of its exposed area oximorphic features inside (former) soil aggregates that are black or have a redder hue and a higher chroma than the surrounding material; large contents of Fe oxides, at least in the oximorphic features; not continuously cemented
Sombric horizon	Subsurface accumulation of organic matter other than in spodic or natric horizons; not a buried surface horizon
Spodic horizon	Subsurface accumulation of Al with Fe and or organic matter
Tsitelic horizon	Lateral accumulation of Fe, usually derived from Planosols and Stagnosols further upslope
6. Other mineral diagnostic horizons	
Albic horizon	Light-colored; loss of colored substances (e.g. oxides, organic matter) due to soil-forming processes
Cambic horizon	Evidence of soil-forming processes; not meeting the criteria of diagnostic horizons that indicate stronger alteration or accumulation processes
Cohesic horizon	Massive or subangular blocky structure, root penetration restricted, drainage normally free, rich in kaolinite, poor in organic matter
Ferrallic horizon	Strongly weathered; dominated by kaolinites and oxides
Fragic horizon	Structure that roots and percolating water penetrate only along interped faces; non-cemented
Nitic horizon	Rich in clay minerals and Fe oxides, moderate to strong structure, shiny soil aggregate surfaces
Panpaic horizon	Buried mineral surface horizon with a significant content of organic matter formed before having been buried
Protovertic horizon	Influenced by swelling and shrinking clay minerals
Vertic horizon	Dominated by swelling and shrinking clay minerals

^aThe actual definitions are more detailed and specific. For diagnostic criteria please refer to WRB, IUSS Working Group WRB (2022).

Table 3 Diagnostic properties and materials of the WRB^a.

<i>Diagnostic feature</i>	<i>Description</i>
1. Diagnostic properties related to surface characteristics	
Takryic properties	Fine-textured surface crust with a platy or massive structure, under arid conditions in periodically flooded soils
Yermic properties	Combination of desert features: desert pavement, varnishing, ventifacts, vesicular pores, platy structure
2. Diagnostic properties defining the relationship between two layers	
Abrupt textural difference	Very sharp increase in clay content within a limited depth range
Albeluvic glossae	Interfingering of coarser-textured and lighter colored material into an argic horizon forming vertically continuous tongues (special case of retic properties)
Lithic discontinuity	Differences in parent material
Retic properties	Interfingering of coarser-textured and lighter colored material into an argic or natric horizon
3. Other diagnostic properties	
Andic properties	Short-range-order minerals and or organo-metallic complexes
Anthric properties	Applying to soils with mollic or umbric horizons, if the mollic or umbric horizon is created or substantially transformed by humans
Continuous rock	Consolidated material (excluding cemented pedogenetic horizons)
Gleyic properties	Saturated with flowing or upwards moving groundwater (or upwards moving gases), permanently or long enough that reducing conditions occur
Protocalcic properties	Carbonates derived from the soil solution and precipitated in the soil (secondary carbonates), less pronounced than in calcic or petrocalcic horizons
Protogypsic properties	Gypsum derived from the soil solution and precipitated in the soil (secondary gypsum), less pronounced than in gypsic or petrogypsic horizons
Reducing conditions	Low rH value and or presence of sulfide, methane or reduced Fe
Shrink–swell cracks	Open and close due to swelling and shrinking of clay minerals
Sideralic properties	Relatively low CEC
Stagnic properties	Saturated with surface water (or intruding liquids), at least temporarily, long enough that reducing conditions occur
Vitric properties	≥ 5% (by grain count) of volcanic glasses and related materials, and containing a limited amount of short-range-order minerals and or organo-metallic complexes
4. Diagnostic materials related to the concentration of organic carbon or to organic artifacts	
Mulmic material	Developed from water-saturated organic material after drainage; 8–20% soil organic carbon
Mineral material	< 20% soil organic carbon and < 35% (by volume) organic artifacts
Organic material	≥ 20% soil organic carbon
Organotechnic material	< 20% soil organic carbon and ≥ 35% (by volume) organic artifacts
Soil organic carbon	Organic carbon that does not meet the diagnostic criteria of artifacts
5. Diagnostic material related to color	
Claric material	Light-colored fine earth, expressed by high Munsell value and low chroma
6. Technogenic diagnostic materials	
Artifacts	Created, substantially modified or brought to the surface by humans; no subsequent substantial chemical or mineralogical change of properties
Technic hard material	Consolidated and relatively continuous material resulting from an industrial process
7. Other diagnostic materials	
Aeolic material	Deposited by wind
Calcaric material	≥ 2% calcium carbonate equivalent, at least partially inherited from the parent material
Dolomitic material	≥ 2% of a mineral that has a ratio $\text{CaCO}_3/\text{MgCO}_3 < 1.5$
Fluvic material	Fluviatile, marine or lacustrine deposits with evident stratification
Gypsic material	≥ 5% gypsum, at least partially inherited from the parent material
Hypersulfidic material	Containing sulfides and capable of severe acidification
Hyposulfidic material	Containing sulfides and not capable of severe acidification
Limnic material	Deposited in water by precipitation (possibly with sedimentation), or derived from algae, or derived from aquatic plants with subsequent transport or subsequent modification by aquatic animals or microorganisms
Ornithogenic material	Excrements or remnants of birds or bird activity
Solimovic material	Heterogeneous mixture that has moved down a slope, suspended in water or by plowing; dominated by material that has undergone soil formation at its original place.
Tephric material	≥ 30% (by grain count) volcanic glass and related materials

^aFor definitions and diagnostic criteria, please refer to WRB, IUSS Working Group WRB (2022).

accord with the criteria and definitions of the WRB, in the 4th edition of the WRB (IUSS Working Group WRB, 2022) a field guide has been included. Once the diagnostics have been determined, they are compared with the key to identify the Reference Soil Group. For the second level of classification, qualifiers are put before and after the name of the RSG. The qualifiers that apply to the RSG are listed in the key. The principal qualifiers are added before the name of the RSG starting with the first principal qualifier that applies closest to the RSG name, and then the second and next ones consecutively left of the previous qualifier. The supplementary

Fig. 2 Example of a diagnostic horizon: a vertic horizon is a clay-rich (>30%) subsurface horizon with slickensides and wedge-shaped soil aggregates that result from shrinking and swelling: (A): tilted shear plane of a slickenside; (B): wedge-shaped element, both A and B are formed by swelling of the soil under moist conditions. (C): deep shrink cracks formed when the soil is shrinking under dry conditions. Vertisol, Jordan. Images: Stephan Mantel.

Fig. 3 Diagnostics of a volcanic soil in Goðafoss, Iceland: a mollic horizon (0–45 cm) with vitric properties (volcanic glass 20–91 cm), and with andic properties (0–100 cm), with allophane, imogolite and similar minerals predominating (Silandic). The soil classifies in WRB2022 as a Mollic, Vitric, Silandic Andosol (Siltic, Eutrosilic, Humic) and in Soil Taxonomy as a Medial, amorphic Eutric Pachic Fulvicryand. Image: Stephan Mantel.

qualifiers are placed between brackets to the right of the name of the RSG. Qualifiers related to the texture, if applicable, are the first in the list. All other supplementary qualifiers follow these in alphabetical order and are separated by commas. Subqualifiers can be created, by addition of specifiers to the qualifier name, and added for specific conditions. For example, to specify that a particular qualifier occurs in the depth range of 0 to 50 cm, the specifier Epi- (from Greek *epi*, over) can be added. Other examples of specifiers are those related to buried conditions (Thapto-), properties occurring at greater depth (Bathy-) or weaker expression (Proto-). The position of the subqualifier in the name of the soil is regulated by specific rules.

Apart from the addition of a field guide for soil description, the 4th edition of the WRB differs from previous editions by the addition of new definitions such as: fine earth, litter layer, soil surface, mineral soil surface, soil layer and soil horizon. The field guide also includes an example field description sheet that is made available online. Many of the definitions in the new field guide were sourced from the USDA (United States Department of Agriculture) Soil Survey Manual (Soil Science Division Staff, 2017) and the NRCS (Natural Resources Conservation Service) Fieldbook (NRCS–USDA, 2012), which brings the WRB and Soil Taxonomy closer together.

An example

An example of a full classification in WRB 2022 is the soil in Fig. 4 from the steppes in Mongolia, that was described and classified during the WRB field workshop in 2019.

Name: Cambic **Kastanozem** (Pantoloamic, Endoskeletal, Endoraptic).

Description and diagnostics:

0–20 cm: Ah, mollic horizon, 10YR 3/3, sandy loam, pH 7.14;

20–40 cm: Bw, cambic horizon, sandy loam, pH 7.36;

40–55 cm: Ck, sandy loam with gravels, protocalcic, pH 7.61;

Fig. 4 A Cambic Kastanozem under short-grass steppe vegetation in Mongolia. Image: Stephan Mantel.

Fig. 5 Polygenetic soils, (A): multiple panpaic horizons (buried A-horizons) in a backswamp soil (Eutric Gleysol) in the Netherlands, (B): a panpaic horizon in an Andosol on a hillslope in Buthan. Images: ISRIC World Soil Information (l), Thomas Caspari (r).

55–90 cm: C, sandy loam, pH 7.85;
 90–140 cm: 2C, sandy loam, skeletal;
 140– (180) cm: 3C, loamy sand.

Buried soils

A special case in soil description and classification is that of buried soils. A soil is buried when it is covered by younger deposits. This may even be in repeated cycles. Fig. 5 shows examples of polygenetic soils with buried surface horizons consisting of mineral material and a significant amount of organic matter. In the 4th edition of WRB a buried organic-matter-rich A horizon is recognized as a panpaic horizon. This diagnostic horizon occurs in various landscapes and is the result of geomorphological processes, i.e. deposition of transported material.

In the case of buried soils, the following rules apply. The overlying material and the buried soil are classified as one soil if together they qualify as a Histosol, Anthrosol, Technosol, Cryosol, Leptosol, Vertisol, Gleysol, Andosol, Planosol, Stagnosol, Arenosol, Fluvisol or Regosol. Otherwise, the overlying material is classified with preference, if it is ≥ 50 cm thick (unless the overlying soil is a Regosol). In all other cases, the buried soil is classified with preference. If the overlying soil is classified with preference, and the underlying soil is not a Regosol or Leptosol, and shows a complete horizon sequence, and one soil does not influence the pedogenic processes in the other soil, then the name of the buried soil is placed after the name of the overlying soil adding the word 'over' in between, e.g. Skeletic Umbrisol (Siltic) over Albic Podzol (Arenic). Otherwise, a buried diagnostic horizon or a buried layer with a diagnostic property is added with the Thapto- specifier to the name of the overlying soil. If the buried soil is classified with preference, the overlying material is indicated with the Novic qualifier.

Major changes in the WRB 2022 edition

In the 4th edition of the WRB some diagnostics have been removed, some new ones added, and definitions were improved where needed. Among the diagnostics that have been taken out are the fulvic and the melanic horizons (dark topsoils associated with allophane), as these concepts have not proven to be useful for understanding soil organic matter dynamics or soil quality (Wander, 2004). The aridic properties, a soil condition that is actually defined by climate characteristics, have also been taken out. The geric property is not retained as diagnostic, but can be expressed as a qualifier. The reformulation of the hyper- and hyposulfidic material

makes the term sulfidic redundant as a diagnostic. Newly introduced are: albic horizon (light colored and eluviated), cohesic horizon (dense subsurface horizon dominated by kaolinite), limonic horizon (with accumulation of Fe by capillary rise in groundwater soils, traditionally referred to as bog iron), panpaic horizon (buried A horizon), tsitelic horizon (has accumulation of Fe by subsurface flow), protogypsic properties (accumulation of secondary gypsum, not sufficient for a gypsic or petrogypsic horizon), aeolic material (deposited by wind), mulmic material (mineral material with a high content of soil organic carbon, derived from organic material), organotechnic material (containing large amounts of organic artifacts and relatively small contents of soil organic carbon in the fine earth).

Some diagnostic materials received new names, such as 'claric material' instead of 'albic material' (to avoid confusion with the re-introduced albic horizon), 'solimovic material' instead of 'colluvic material' (colluvium appeared to refer to many different concepts; see [Miller and Juilleret, 2016](#)). Various criteria in the diagnostics, in the key and in the definitions of the qualifiers were reformulated and refined.

The WRB and soil taxonomy

Both the WRB and Soil Taxonomy (ST) are endorsed by the IUSS as the two international soil classification systems. The WRB and Soil Taxonomy have a common basis in that the classification hinges on diagnostic features relating to soil morphology, and physical and chemical properties. Even though the diagnostics reflect soil formation processes, soils are classified based on precisely defined diagnostic features rather than on soil-forming processes, which was the case in older classification systems. A major difference between the WRB and Soil Taxonomy is that soil climate is not used as a differentiating characteristic in the WRB.

Furthermore, with six levels of soil classification Soil Taxonomy has a more elaborate hierarchical structure than WRB. The 12 soil orders at the highest level are further subdivided into suborders, great groups, subgroups, family, and series. Because of differing criteria, definitions and concepts between the RSGs and Soil Orders, it is not possible to have a one-to-one conversion between the two systems. However, it is possible to indicate similarities between some of the RSGs and Soil Orders; there is a good match between the Histosols (WRB/ST), Cryosols (WRB) and Gelisols (ST), Vertisols (WRB/ST), Andosols (WRB) and Andisols (ST), and Cambisols (WRB) and Inceptisols (ST). The Chernozems, Kastanozems and Phaeozems of the WRB, which are soils with different expressions of dark, organic-matter-rich A horizons, correspond to the Mollisols in Soil Taxonomy. The highly weathered tropical soils such as Ferralsols and Plinthosols have similarity with Oxisols in Soil Taxonomy (Plinthaquox for Plinthosols). The soils related to arid climates and saline soils in WRB, such as the Solonetz, Solonchaks, Gypsisols, Calcisols and Durisols, are mostly accommodated in the order of the Aridisols of Soil Taxonomy, or correspond to some suborder level, such as: Solonetz (WRB) with Natrargids (ST), Solonchaks (WRB) with Salorthids (ST), Gypsisols (WRB) with Gypsids (ST), Calcisols (WRB) with Calcids (ST) and Durisols (WRB) with Durids (ST). The soils with clay illuviation and different clay mineralogy and base saturation in the WRB, the Nitisols, Retisols, Acrisols, Lixisols, Alisols, and Luvisols, correspond to different suborders of the Ultisols and Alfisols in Soil Taxonomy. The young, little developed soils group in the WRB, the Leptosols, Fluvisols, Arenosols and Regosols, correspond to the Entisols of Soil Taxonomy. A special case is the Umbrisols (soils with a dark topsoil and low base status) which in Soil Taxonomy will mostly be classified as Inceptisols. Anthropogenic soils, or soils with human-transported material in Soil Taxonomy, are recognized with a combination of taxa at the subgroup and family levels ([Galbraith and Shaw, 2017](#)), such as Plaggic Anthroisol (WRB) corresponding to the Plagganthrept and Plaggept (ST).

Application of the WRB

The term Reference Base indicates the common denominator function of the WRB, whereby the RSGs have sufficient width to facilitate harmonization and correlation with national classification systems. In addition, the WRB also serves as a communication tool for compiling global soil databases and for the inventory and monitoring of the world's soil resources. The nomenclature used to distinguish soil groups retains terms that have been used traditionally or that can be introduced easily into common language. The wide acceptance of the WRB can be attributed to three factors: (1) it is not intended to replace any existing system, but rather to facilitate communication and correlation between national and local systems; (2) it does not attempt to provide names for detailed maps and so does not interfere with local initiative; (3) it is based on extensive field experience and thus forms a useful stratification of the soil universe at high to medium categorical levels ([Rossiter, 2007](#)).

The WRB is used in several countries and projects as a basis for soil classification and for soil mapping. Several countries have produced a subnational or national soil map based on the WRB for exchange and correlation, e.g. the Flemish region ([Dondeyne et al., 2014](#)), Hungary ([Dobos et al., 2019](#)). The WRB is accepted as the common classification system for the European Union. Other examples of production of WRB maps at the national scale in addition to the existing national soil maps are the [national soil map for England and Wales](#) and [Scotland](#), the soils of Italy that have been mapped in the WRB at different scales ([Costantini and Dazzi, 2013](#); [Napoli et al., 2005](#)) and of Romania at 1:200.000 scale ([Vlad et al., 2012](#)). Maps at continental and regional level have been produced of which the soil atlases edited by the Joint Research Centre of the European Commission are good examples; for Latin America and the Caribbean ([Gardi et al., 2014](#)), for Europe ([Jones et al., 2005](#)), the [Northern Circumpolar Region](#) ([Jones et al., 2010](#)) and for Africa ([Jones et al., 2013](#)).

Legacy maps and reports are also increasingly becoming available in digital format. The online libraries of [ISRIC](#) (International Soil Reference and Information Centre, now ISRIC World Soil Information) the [WOSSAC](#) (World Soil Survey Archive and Catalog) library of Cranfield University, The [library of the European Soil Data Centre](#) (ESDAC) of the Joint Research Centre and the online [FAO soils portal](#) all have digitized legacy documents accessible. These maps and data are increasingly being used as input in digital soil mapping approaches. For example, for mapping soil units (RSGs with principal qualifiers) at district level in Ethiopia ([Leenaars et al., 2020](#)) but also at global level in the [Soilgrids](#) global digital soil mapping system ([Hengl et al., 2017](#); [Poggio et al., 2021](#)). Alternatively, WRB soil mapping units have proven useful covariates for predicting soil organic carbon hotspots in Belgium ([Ottoy et al., 2022](#)). Various databases contain information on the FAO-revised legend and or WRB classification for soil profiles, such as the global database of the World Soil Information Service ([WoSIS](#)), the Africa Soil Profiles Database ([AfSP](#)), the Harmonized World Soil Database ([HWSD](#)), the Soil and Terrain Databases ([SOTER](#)). These databases have also been used to predict e.g. soil hydraulic properties of the Zambezi River Basin ([Kalumba et al., 2022](#)) or soil nutrient status in Africa ([Hengl et al., 2021](#)), for example.

Creating map legends

In classifying individual soils, all applicable (sub)qualifiers are used to name the soil. For the creation of map legends, the number and nature of qualifiers depend on the scale and purpose of the map. For maps at continental or regional scales only the dominant Reference Soil Group may be used, without qualifiers. For next larger map scales, the RSG plus the first applicable principal qualifier can be used. For more detailed maps, the RSG plus the first two applicable principal qualifiers can be considered. The principal qualifiers are indicated before the RSGs, just as for naming a soil. Further qualifiers may be added, depending on the purpose and scope of the map. These may be principal qualifiers from further down the list, not already used in the soil name, or supplementary qualifiers placed according to rules for supplementary qualifiers.

The WRB in education

Various courses are provided on the WRB, and educational materials have been compiled. Examples include courses provided by Nicolaus Copernicus University (Department of Soil Science and Landscape Management) in Toruń that have made available a series of [atlases and guidelines](#). Various courses are offered, often with field excursions and practice, such as a Spring School course by ISRIC World Soil Information, and the summer [WRB Soil Classification Intensive Field Workshop](#) organized in Toruń. Many Universities offer lectures dedicated to, or that include the WRB. The [Lecture Notes on the Major Soils of the World](#) ([Driessen et al., 2001](#)) has proven to be a great resource over many years for both students and lecturers as a guide to soils of the world, and has possibly contributed to the use and acceptance of WRB in teaching and research. The recently published textbook ‘Soils of the World’ ([Zech et al., 2022](#)) presents the world soil geography following the 3rd edition of the WRB. The World Soil Museum has made the soil reference collection of ISRIC World Soil Information accessible via components of the virtual soil museum, such as a [soil explorer](#) that provides access to high resolution images of soil monoliths and to the [ISIS](#) (ISRIC Soil Information System) soil reference database (including soil and site descriptions, physical and chemical data and field images) and a [world map](#) with soil profiles that can be viewed at the sample location (allowing one to zoom in at field level on remote sensing images). Online visitors can explore the World Soil Museum via an online [indoor tour](#). The University of Leuven has developed an [educational platform](#) for soils and landscapes of the world drawing on data from their own collections and from the ISRIC Soil Information System. The KU Leuven has also developed, with contributions from ISRIC, a Massive Open Online Course (MOOC) on [soils of the Tropics](#), in which various RSGs from WRB are highlighted. The Technical University of Munich has developed [instructional videos](#) on how to describe a soil according to the FAO Guidelines for Soil Description ([FAO, 2006](#)) and how to do a soil classification with the WRB (2014, update 2015).

Abstract

Soil Taxonomy, a soil classification system, was created to help organize knowledge about soils. Soils are grouped into 12 orders in the system based on soil forming processes and soil attributes. Soil Taxonomy incorporates climate by using the soil moisture and the temperature regimes to define lower categories. The system enables soil–landscape relationships to be established and accounts for all known soils in addition to facilitating soil management in a sustainable manner. Soil Taxonomy is a powerful tool for soil quality assessments and mitigation measures.

Key points

- To enable the reader to be familiar with the basics of Soil Taxonomy
- To show how soil classification is linked to soil management
- To illustrate the importance of soil classification in maintaining soil health

Introduction

Soil is commonly described as the mantle or the skin covering the landmass of the Earth. For most people, soil is the natural medium for vegetation growth and its thickness determined by the rooting depth of plants. It is composed of solids (mineral and organic), liquids and gases. The upper limit of the soil is the contact between soil and air or shallow water, to a depth of several meters. Soil on the landscape is a continuum that eventually grades into non-soil materials such as rock, ice, or deep water.

Pedology is the study of soils which is conducted by pedologists or soil scientists. Conventionally, pedologists study the zone of the soil from its upper limit to a depth of about 200 cm, unless non-soil material occurs at a shallower depth. This is the zone where maximum biological or pedological processes occur. Occasionally, pedologists analyze the soil to depths of 20 m or more for special studies. There are five factors of soil formation: climate, topography, parent material, time, and biological activities (Jenny, 1941). Variations in these factors can result in a range of soils that differ in their physical, chemical, biological, and mineralogical properties. Therefore, it is important to know how soils form and what differences exist among them as further explored in Buol et al. (2011). Further information about soil forming processes and characteristics is available in other chapters of the Encyclopedia.

Soil classification

Soil classification systems were created to help organize knowledge about soils (Arnold et al., 1997; Ahrens and Arnold, 2000). An important difference between the classification of soils and that of plants and animals is that unlike the latter, soil is not discrete but a continuum and therefore the boundaries between named soils are abrupt and artificial. Depending on the objectives for which the classification was created, the class definitions and the structure of the classification system may vary (Arnold, 1990). Many countries have national soil classification systems but the two that are widely used and employed throughout the world are Soil Taxonomy (Soil Survey Staff, 1975, 1999; Wilding et al., 1983a,b) and the World Reference Base, IUSS Working Group WRB (2015).

Soil surveys enable the creation of maps of soil characteristics that provide information on the management of soil properties. These surveys provide the description, classification, and delineation of soils across the landscape. Specialized maps with soil classifications (Bartelli, 1978; Orvedal and Edwards, 1941) are produced for specific objectives (Benchmark Soils Project, 1982; USDA-SCS, 1991; Libohova et al., 2020). Soil maps are also produced at different scales: detailed maps (1:10,000 or larger scale) to show soils on farms and general maps (1:100,000 or smaller scale) to depict soils over large areas such as countries, continents, or the world. Map units appear as polygonal areas and group soils based on their similarities (Soil Science Division Staff, 2017).

To appreciate the variety of soils that occur on the planet, it is necessary to understand the classification system being used since many classification systems exist. These systems provide information on their physical and chemical properties from which an understanding of their potential specific uses can be based. Two classification systems that are widely used are the World Reference Base (Deckers et al., 1998; IUSS Working Group WRB, 2015; Schad, 2017) for soil classification that was initiated by the Food and Agriculture Organization of the United Nations (FAO), while Soil Taxonomy (Soil Survey Staff, 2014) is a system developed in the United States with the collaboration of international soil scientists and is a natural classification system. Nearly half of the world's countries use Soil Taxonomy as their National Soil Classification system, and many others use it in conjunction with other systems and include Soil Taxonomy in technical reports. In addition, Soil Taxonomy has been accommodating other soil classification systems by serving as a common platform for communication and exchange of technology for more than half a century.

Soil Taxonomy has six categories as listed in Table 1. The soil series is the lowest category and is defined with the maximum amount of detailed information. Information is generalized in the definition of each higher category. Consequently, each category can only be used for specific purposes. When employed to designate map units, the scale of the maps limits the category that is represented as shown in Table 1. The highest category, the order, has only 12 classes. There are 64 classes in the suborder, 300 classes in the great group, and 2400 classes in the subgroup (Soil Survey Staff, 2014). In the United States, 24,858 soil series have been established but there are no estimates for the total number of soil series in the world. Therefore, at each level, the amount and quality of information delivered for mapping and interpretative purposes is largely controlled by the scale of observation. Onsite soil management is done at the series level but as we move higher in the Taxonomy, the dominance of soil forming factors in defining the soil orders, for example, assists in defining appropriate strategies for management at that level.

Fig. 1 shows the global distribution of the 12 soil orders in Soil Taxonomy, while Fig. 2 shows soil profile examples of each order, and how remarkably different they are from each other. Soil forming processes (Table 1) and the attributes they provide for the soil are used to define the soil. Major differentiating criteria for each soil order have been generalized and listed in Table 2. Soils are generally composed of mineral and organic materials. In general, in Soil Taxonomy, it is the presence or absence of subsurface horizons and their characteristics that are used to separate the orders. For example, dominance of short-range order minerals such as allophane and imogolite in Andisols, smectitic clays in Vertisols, organic matter in Histosols, and low-activity clays in Oxisols, each impart characteristics that are used to define specific groupings of soils. The second group of soil processes listed in Table 2, have horizons of accumulation or depletion. The next group of soils (Inceptisols and Gelisols) also develop from soil forming processes, but the manifestations are slight or mainly physical. Finally, the last group contains the Entisols. These are soils where the original material is least altered or not modified by soil forming processes. Each order of soils also has specific subordinate properties that are used to define the lower categories.

Global distribution

Climate or hydrology controls many of the soil forming processes, therefore, each of these major kinds of soils has a specific place on the landscape (Fig. 3). However, each soil may have properties transitional to other soils and such secondary features are used to define the intergrades of the lower categories. Soil Taxonomy incorporates climate by using the soil moisture regime (SMR) as shown in Fig. 3 and the soil temperature regime (STR) to define lower categories. Soils with an aridic SMR (deserts) occupy about 30% of the total global land area. These soils are very dry and are only suitable for agriculture if there is a source of irrigation. Soils with a xeric SMR (Mediterranean like climate) occur in areas where precipitation occurs in winter, and like those with a ustic SMR (semi-arid) have moisture stress for prolonged periods during the year. These two groups of soils occupy about 28% of the land and form the semi-arid zones where crops require supplemental irrigation. The soils with an aquic SMR represent wetlands, where the soil is saturated for long enough to cause anaerobic conditions. About 24% of the total land is relatively free from moisture stress (udic and perudic SMRs) although some areas have low temperatures. The very cold permafrost (permanently frozen) soils, which occupy about 5.4% of the land, are the tundra regions. Soils with intermittent permafrost (interfrost) are generally under boreal forest, but are cultivated in some areas with an annual grain crop of short duration. Soils with mesic, thermic, isomesic, and

Table 1 Defining characteristics of the categories in Soil Taxonomy.

Category	Definition	Functions	Potential uses
Order	Soils having properties (marks) or conditions, resulting from major soil forming processes that are sufficiently stable in a pedologic sense and that help to delineate broad zonal groups of soils.	Depict zones where similar soil conditions have occurred for general understanding of global patterns of soil resources; Establish global geographic areas within which more specific factors and processes result in the diversity of soils.	General global/continental/regional assessment; Global climate change studies. AMS: <1:10,000,000 MSD: >40,000
Suborder	Soils within an order having additional properties or conditions that are major controls or reflect such controls, on the current set of soil forming processes and delineate broad ecosystem regions.	Demarcate broad areas where dominant soil moisture conditions generally result from global atmospheric conditions; Delineate contiguous areas with similar natural resource endowments; Ecosystems with distinct vegetation affinities usually determined by limiting factor/s of soil moisture or conditions.	Demarcate areas in regions or large countries for assessment and implementation of economic development; Analysis of international production and trade patterns; Priority setting for multi-purpose uses of land resources. AMS: 1:1,000,000 to 1:10,000,000 MSD: 4000–40,000
Great Group	Soils within a suborder having additional properties that constitute subordinate or additional controls, or reflect such controls, on the current set of soil forming processes including landscape-forming processes.	To demarcate contiguous areas with similar production systems or performance potentials.	Development of strategic plans for regional development; Basis for coordinating national resource assessment and monitoring programs; Infrastructure development to assure equity in development; AMS: 1:250,000 to 1:1,000,000 MSD: 250–4000
Subgroup	Soils within a great group having additional properties resulting from a blending or overlapping of sets of processes in space or time that cause one kind of soil to develop from, or toward, another kind of soil: <i>Intergrades</i> show the linkage to the great group, suborder, or order level; <i>Extrgrades</i> have sets of processes or conditions that have not been recognized as criteria for any class at a higher level, including non-soil features; The soil is considered as the “typic” member of the class if the set of properties does not define intergrades or extrgrades.	To demarcate production land units with similar land use and management requirements.	Targeting research and development for specific land use or cropping systems; Implementing conservation practices and ecosystem-based assistance; Community development projects and monitoring sustainability. Basis for diversification of agriculture and uses of land resources; Basis for implementing environmental management programs and modeling ecosystem performance. AMS = 1:100,000 to 1:250,000 MSD: 40–250
Family	Soils within a subgroup having additional properties that characterize the parent material and ambient conditions; The three most important properties are particle size, mineralogy, and the soil temperature regime.	Demarcate resource management domains characterized by similar management technology and production capabilities.	Basic units for extension/technology transfer; Modeling cropping systems’ performance; Addressing socioeconomic concerns. AMS: 1:25,000 to 1:100,000 MSD: 2.5–40
Series	Soils within a family having additional properties that reflect relatively narrow ranges of soil forming factors and processes, determined by small variations in local physiographic conditions, that transform parent material into soil.	To delineate land units for site-specific management of farms.	Implementing soil-specific farming; Designing farm-level conservation practices. AMS: >1:25,000 MSD: <2.5

AMS, appropriate map scale.

MSD, minimum size delineation; smallest area that can be delineated on a map with a legible identification; in hectares.

Oxisols	Mollisols		
Vertisols	Spodosols		
	Aridisols		

isothermic STRs are generally those with the highest agricultural potential if adequate soil moisture is available. The humid tropical soils are represented by the combination of an isohyperthermic or isothermic STR and udic, perudic or aquic SMRs. These humid tropical soils occupy about 9% of the land surface and are not only some of the poorest soils for agriculture but are also subject to heavy incidence of pests and diseases. Each combination of SMR and STR represents a unique pedo-environment that supports the development of distinct soil properties.

The global soil regions map (Fig. 1) was created using the Harmonized World Soil Database (HWSD) (FAO/IIASA/ISRIC/ISS-CAS/JRC, 2012) and modeled SMRs (Fig. 3) using the Newhall Simulation model (USDA-NRCS, 2011) with climatic data from <https://WorldClim.org> (Hijmans et al., 2005). Soil Taxonomy orders and suborders were assigned to each combination of the HWSD soil class and SMRs.

Estimates of the distribution of the soil orders and suborders across SMRs is presented in Table 3. Entisols occupy about 20% of the land, making it the largest single order in the world. Inceptisols occupy about 12% of the land. Even though these two soil orders are present in a range of climatic conditions, it appears that the Inceptisols are mostly dominated by those that occur in wet areas, whereas most of the Entisols occur under drier moisture conditions. The Aridisols (11% of the land) are dominated by soils that have special horizons such as calcic, petrocalcic, argillic, or natric horizons. The Histosols, Andisols, and Vertisols collectively occupy less than 4% of the total land area. These are soils formed in special materials and occupy specific geographic areas. The Gelisols (6.5%) are confined to the very cold regions of the world. Due to intense weathering and leaching in hot humid environments, most of the Oxisols (6%) and Ultisols (8%) are in tropical or subtropical zones. Although they are more extensive in the temperate regions, Alfisols (9%) and Mollisols (8%) are found under a wide range of SMRs and STRs. Inceptisols and Entisols, as mentioned earlier, are present under a range of climatic environments.

The properties used in Soil Taxonomy classification are easily observed in the field using reliable techniques such as the Munsell soil color chart to characterize the soil colors even in mottled horizons, measurements of soil temperature, permeability and even acidity. This includes properties that are seasonally dynamic such as fluctuations in soil moisture or temperature conditions,

Fig. 3 Global soil moisture regimes map.

Table 3 Estimates of area occupied by major soils of the world.

changes in nutrient properties, water-table levels, soil organic matter content, soil carbon contents and freeze–thaw cycles. The structure of Soil Taxonomy was created to classify soils that currently exist and to have the capability to be modified to account for new soil types. To do this, the definitions and nomenclature used must always deliver exactly the same meaning to everyone.

Gelisols

These soils commonly occur in areas where the mean annual soil temperature is less than 0 °C. They are frozen for long periods of the year and thaw out during the short warmer spells (Bockheim and Tarnocai, 2000). The freezing and thawing processes promote physical changes and mixing of the soil called cryoturbation or frost churning. If there is sufficient water and the warm period is long enough, vegetation can grow, and organic matter accumulates on the soil, leading to the development of organic-rich soils or peat. These arctic soils have unique features such as ice lenses, ice wedges, or other frozen features below the surface. The presence of permafrost and other soil features from freezing and thawing cause irregular or broken horizons and incorporation of organic materials into the soil profile. This process increases soil volume and reduces bulk density. In cold arid areas, the soil particles are frozen together by dry permafrost. Dry permafrost occurs when the soil temperature remains below 0 °C but there is insufficient moisture to be cemented by ice.

The three suborders in Gelisols are:

Histels (1.45% of land area): These soils have an organic surface (histic epipedon) and may be underlain by ice wedges, permafrost, or bedrock.

Turbels (4.15% of land area): Contain disrupted horizons caused by cryoturbation or frost churning that mixes the soil through freeze-thaw process. Fig. 2 includes a Turbel soil profile from Alaska.

Orthels (0.89% of land area): Other Gelisols that do not meet other subgroup criteria and are mostly found in North America and in some parts of Europe and Asia.

Histosols

Histosols are soils that dominantly consist of organic soil materials (Rabenhorst and Swanson, 2000). Histosols comprise a small portion of the world's land area (0.59%) but are widely distributed irrespective of climate. They develop where the rates of organic matter accumulation exceed decomposition and removal. These soils are commonly referred to as bogs, moors, marsh, swamps, or fens.

The suborders of Histosols are separated by the degree of decomposition of the organic matter, and climate. These are:

Folists (0.02% of land area): Are not saturated with water for more than a few days per year; they consist of horizons formed by the decomposition of leaves, twigs, and branches at the soil surface. The organic materials accumulate in aerobic conditions where the climate is cool and humid enough to reduce decomposition. They occupy a small area mainly in the northern latitudes.

Fibrists (0.15% of land area): Consist largely of plant remains so slightly decomposed that rubbing does not destroy plant fibers and their botanical origin can be easily determined. They occupy large areas in the northern latitudes.

Hemists (0.14% of land area): Consist of organic materials that are so decomposed that the botanic origin of as much as two-thirds of the plant materials cannot be readily discerned or the fibers can be largely destroyed by rubbing between the fingers. They occupy small areas in the northern latitudes and may also be found in the tropics.

Saprist (0.28% of land area): Consist of almost completely decomposed plant remains and their botanic origin cannot be determined. Most of these soils are found in warmer regions with mesic, thermic, and hyperthermic STRs. Fig. 2 includes a Saprist soil profile from Florida.

Wassists (not included in this assessment): Have a positive water potential at the soil surface for more than 21 h of each day in all years and are permanently submerged soils in fresh and saltwater environments (Soil Survey Staff, 2014).

Andisols

Andisols are soils formed on volcanic ash that have andic soil properties derived from aluminum–humus complexes (Kimble et al., 2000). The Andisols have a mineralogical composition comprising volcanic glass, short-range order minerals such as allophane and imogolite, and variable amounts of halloysite. This mineralogical association results in unique soil properties, such as high phosphate fixing capacity, low cation retention, and a high water holding capacity. They are dominantly found along the circum-Pacific belts but occur sporadically elsewhere (0.72% of the landmass).

Eight suborders are recognized in the Andisols. These are:

Aquands (land area too small for map scale): These soils experience water saturation for prolonged periods during the year.

Cryands (0.18% of land area): These soils have a cryic STR (mean annual soil temperature between 0 °C and 8 °C).

Gelands (0.12% of land area): These soils have a gelic STR (mean annual soil temperature less than 0 °C).

Torrands (0.01% of land area): These soils have an aridic SMR.

Xerands (0.01% of land area): These soils have a xeric SMR.

Vitrands (0.11% of land area): These soils are recent ash or cinder deposits where some weathering and soil formation has taken place.

Ustands (0.05% of land area): These soils have an ustic SMR. They are widespread on the lee-ward side of tropical volcanoes and are commonly used for agriculture.

Udands (0.26% of land area): These soils have an udic SMR and are widely used for agriculture. Fig. 2 includes an Udand soil profile from Japan.

Spodosols

These soils have a black, reddish brown to strong brown spodic subsurface horizon (spodic horizon) that is high in illuvial organic matter, aluminum (Mokma and Evans, 2000) and may or may not contain iron. It is often overlain by a gray to light gray eluvial horizon.

Five suborders are recognized in Spodosols. These are:

Aquods (0.10% of land area): These soils have an aquic SMR and are generally found in depressions. Fig. 2 includes an Aquod soil profile from Florida.

Gelods (3.03% of land area): Spodosols that have a gelic STR. These are the most extensive Spodosols (3.9 million km²) and are dominant in cold temperate areas of the northern latitudes.

Humods (0.11% of land area): Have a spodic horizon enriched with elevated amounts of organic matter. These soils are generally found in cool climates including high elevations in tropical mountains.

Cryods (1.27% of land area): Have a cryic STR.

Orthods (0.61% of land area): Other Spodosols that do not meet the above criteria.

Oxisols

Oxisols are highly weathered soils and often have a reddish, yellowish, or grayish color. They are commonly located on the gentle undulating surfaces of geologically old surfaces in tropical and subtropical regions where they occupy about 8.2 million km² (Beinroth et al., 2000). They contain few weatherable minerals and tend to have high levels of iron and aluminum. These soils are very infertile and require fertilizers for cropping.

Oxisols are present in every SMR. Natural vegetation ranges from tropical rainforests to savannas.

The suborders of the Oxisols are based on the SMR:

Aquoxs (0.71% of land area): Have an aquic SMR and are the very wet Oxisols.

Torrox (0.05% of land area): Have an aridic SMR. Such soils occur in parts of South America and Africa.

Ustoxs (2.38% of land area): Have an ustic SMR. These are the second most extensive suborder of Oxisols.

Peroxs (0.64% of land area): Have a perudic SMR. These represent the most typical Oxisols of the humid zones in parts of South America, Central Africa, and Asia.

Udoxs (2.55% of land area): Have an udic SMR. These are the most extensive of the Oxisols with large areas in South America, Central Africa, Asia, and some of the Pacific Islands. Fig. 2 includes a Udox soil profile from Brazil.

Fig. 4 shows the distribution of Oxisol suborders in Africa. It is evident that the main types of Oxisols at this level of Taxonomy include the Udic, Ustic, Aquic and Perudic moisture regimes. Other factors that control this distribution include relief and geology.

Vertisols

Vertisols are clayey soils, that shrink and swell and have deep, wide cracks that open and close depending on moisture conditions (Coulombe et al., 2000). Most Vertisols are well suited for mechanized farming if there is sufficient rainfall or irrigation water and if appropriate management practices are followed.

Six suborders are recognized in Vertisols based on the SMR or STR.

Aquerts (land area too small for map scale): Wet Vertisols with an aquic SMR.

Cryerts (0.01% of land area): Cold Vertisols with a cryic or gelic STR.

Torrerts (0.71% of land area): Vertisols with an aridic SMR. Fig. 2 includes a Torrert soil profile from Botswana.

Xererts (0.10% of land area): Vertisols with a xeric SMR. These are the typical reddish brown Vertisols that have a Mediterranean climate.

Usterts (1.56% of land area): Vertisols with an ustic SMR. Extensive areas are found in South Asia and Africa.

Uderts (0.17% of land area): Vertisols with an udic SMR. Large areas of Uderts are found in North and South America.

Aridisols

Aridisols are soils that do not have water available to plants for long periods (Southard, 2000). During most of the time when the soil is warm enough for plants to grow in Aridisols, soil water is held at potentials less than permanent wilting point. There is no period of 90 consecutive days when moisture is continuously available for plant growth.

The seven suborders are:

Salids (1.12% of land area): Characterized by the accumulation of salts more soluble than gypsum. These are the typical soils of the playas or desert depressions or closed basins.

Fig. 4 Oxisol suborders in Africa map.

Durids (land area too small for map scale): Characterized by a subsurface cemented layer.

Gypsis (0.95% of land area): Characterized by an accumulation of gypsum. Such soils are extensive in the Middle East.

Argids (2.70% of land area): Characterized by an accumulation of clay by translocation.

Calcids (4.38% of land area): Characterized by an accumulation of carbonates, the soils have a calcic, petrocalcic, or a hypercalcic horizon; these soils are the most extensive of the Aridisols. Fig. 2 includes a Calcid soil profile from New Mexico.

Cambids (1.54% of land area): These soils have a cambic horizon that is characterized by physical or chemical transformations of material.

Cryids (0.29% of land area): Aridisols that have a cryic STR.

Ultisols

Ultisols are similar to Alfisols having a subhorizon of clay accumulation (West and Beinroth, 2000) but have a lower base saturation of cations. Most Ultisols are acid although some may have a high pH in the surface horizons due to agricultural liming.

The suborders of the Ultisols are:

Aquults (0.85% of land area): These are the wet Ultisols with an aquic SMR.

Humults (0.54% of land area): These soils have accumulations of organic matter and usually occur in areas with an udic SMR and cooler temperatures.

Udults (3.65% of land area): These soils have an udic SMR. Fig. 2 includes an Udult soil profile from Vietnam.

Ustults (3.27% of land area): These soils have an ustic SMR.

Xerults (<0.01% of land area): These soils have a xeric SMR.

Mollisols

Presence of a thick dark humus-rich surface horizon (mollic epipedon) is the key feature of Mollisols (Bell and McDaniel, 2000). Most Mollisols are cultivated and sustain high yields of grain crops in the breadbasket regions of the world such as in the United States, Russia, Ukraine, and Argentina.

Eight suborders are recognized in the Mollisols.

Albolls (0.03% of land area): These soils have a bleached subsurface horizon (albic horizon) that is usually wet. Fig. 2 includes an Alboll soil profile from Kansas.

Aquolls (0.20% of land area): These are the wet Mollisols and may have a histic epipedon.

Rendolls (0.20% of land area): These are formed in highly calcareous parent materials and have a udic SMR or cryic STR.

Gelolls (0.97% of land area): Have a gelic STR.

Cryolls (1.46% of land area): Have a cryic STR.

Xerolls (0.53% of land area): Have a xeric or border an aridic SMR.

Ustolls (3.51% of land area): Have a ustic or border an aridic SMR.

Udolls (1.33% of land area): Have an udic SMR.

Alfisols

Alfisols are commonly forested, with moderate to high base saturation (Hallmark and Franzmeier, 2000). Typically, they have a light-colored layer (albic horizon) over a layer of silicate clay accumulation (argillic horizon). They are generally found in climates favorable to crop production; in warm moist climates, they are used to grow many crops.

The five suborders of Alfisols are:

Aqualfs (1.66% of land area): These are the wet Alfisols and have an aquic SMR. Fig. 2 includes an Aqualf soil profile from China.

Cryalfs (1.57% of land area): Have a cryic STR.

Ustalfs (3.76% of land area): Have a ustic SMR.

Xeralfs (0.44% of land area): Have a xeric SMR.

Udalfs (1.99% of land area): Have an udic SMR.

Inceptisols

Inceptisols are soils that are either in the early stages of soil formation and have little soil development (Hudnall et al., 2000) or are soils with well-developed diagnostic horizons that merely fail the criteria of the other soil orders. Most Inceptisols have a cambic horizon and an ochric epipedon.

Six suborders are recognized in the order of Inceptisols.

Aquepts (3.70% of land area): These are the wet Inceptisols that have an aquic SMR.

Gelepts (1.91% of land area): Have a gelic STR.

Cryepts (0.47% of land area): Have a cryic STR.

Ustepts (2.09% of land area): These soils have an ustic SMR.

Xerepts (0.52% of land area): These soils have a xeric SMR.

Udepts (2.98% of land area): These soils have an udic SMR. Fig. 2 includes an Udept soil profile from Idaho.

Entisols

The Entisols have very little or no evidence of soil formation (Nordt et al., 2000). They are most extensive on young alluvial plains or on steep slopes where there is a lack of water movement through the soil. The rate of soil formation may be reduced for several reasons, but generally time has not elapsed since deposition of the material for soil forming processes to act.

Six suborders are recognized in the Entisols:

Aquepts (0.24% of land area): These are the wet Entisols.

Wassents (not included in this assessment): Have a positive water potential at the soil surface for more than 21 h of each day in all years.

Psamments (2.22% of land area): These are the sandy Entisols. Fig. 2 includes a Psamment soil profile from New Hampshire, USA.

Fluvents (2.18% of land area): These are recent alluvial soils showing an irregular decrease in organic matter.

Orthents (15.28% of land area): These are often found on recent erosional surfaces but include all other soils that do not meet the above criteria or criteria for the other soil orders.

Conclusion

Although developed primarily for the soils in the U.S., Soil Taxonomy is applicable world-wide. This system was designed with an open structure to enable modifications to the classification system and can account for new soil properties and soil types, e.g., the non-volcanic andic soils or soil properties. For over six decades, soil scientists from around the world have contributed to the development and application of Soil Taxonomy for soil survey, mapping and interpretation. Soil Taxonomy enables soil-landscape relationships to be identified quite easily and caters for all soils that exist on earth. This allows the information obtained to be used constructively for designing proper decision support systems that result in good practices being advocated to maintain and enhance soil quality. This is particularly important since food security is a major concern for many countries around the world. Therefore, Soil Taxonomy provides an intelligent, open-structured and logical means of maintaining crop production at the desired levels and is flexible enough to cater for inclusions or omissions from the system as deemed necessary. The process of amending Soil Taxonomy requires the existence of the pedon to be established first. After that, the level of placement of the pedon in Soil Taxonomy will be decided based on the main characteristics. The tremendous effort of soil scientists world-wide over the last six decades or so has brought about a comprehensive Soil Taxonomy system that covers all known soil types on Earth. The knowledge pool that has been acquired is very large and has the potential to be applied in new areas as required by respective national space agencies.

A wide diversity of soils exists and each has its own potential and limitations. The performance-related attributes result from the properties and the prevailing environmental conditions. Understanding the soil and its relation to the rest of the environment is important for its sustainable use. Detailed soil surveys provide such information, but most countries of the world lack this information. Assessment and monitoring of the health of our soil resources are essential to their judicious use and management, especially with respect to global environmental changes.

Soil Taxonomy serves as an indispensable tool for decision makers on managing the renewable soil resource in a sustainable manner. This classification system remains a powerful tool for soil quality assessments and mitigation measures.

Acknowledgments

Hari Eswaran coauthored the first edition of this chapter and created the conversion matrix used to determine the global distribution of Soil Taxonomy suborders. Thomas Reinsch provided modifications to the conversion matrix used for this updated chapter. John Kelley provided soil profile images used in Fig. 2. Dan Wing and Charles Kome provided valuable review and suggestions to improve the chapter.

Abstract

Humans have modified soils through time. Soil composition and organization can record information about the history of land use. The investigation of human-influenced soils as archives requires multidisciplinary and multiscale approaches. Human activities have the potential to modify all soil-forming factors and thus influence the evolution of these archives. If the main pedogenic processes observed in human-affected soils are similar to those occurring in natural soils, human-modified soil-forming conditions may reorientate the trajectories of these soils. Improving the knowledge about soil quality and evolution in inhabited areas is necessary to manage the soils of these areas in a sustainable way.

Key points

- Human-modified soils can record information about history of land use.
- Soil composition and organization are markers of human activities.
- Reconstruction of the evolution of these soils requires multidisciplinary and multiscale approaches.
- Human activities modify soil-forming conditions and may create some specific pedogenic trends.
- Knowledge about long-term soil evolution would be of help for managing inhabited areas sustainably.

Introduction

For several millennia, humans have shaped and are shaping the soils in the areas where they live. Through history, human activities have successively modified the soil characteristics and the environmental conditions of soil formation, both intentionally or unintentionally. By modifying the soil properties, human activities alter in the short or long term the capacity of soils to fulfill essential functions and to provide services necessary for the development of human societies (Fig. 1). Soil non-ecological functions include the protection of cultural heritage. Human-modified soils can be considered as recorders of the history of human activity (Urbańska and Charzyński, 2021). For a long time, soils of human-affected areas have received little attention in soil science because of the greater focus on agricultural and forest soils. The investigation of urban, industrial or mining soils started in the 1970s, mainly in relation to the growing public concern about environmental issues and human health. In 1998, a working group dedicated to “Soils of Urban, Industrial, Traffic, Mining and Military Areas” (SUITMAs) was created within the framework of the International Union of Soil Science (IUSS) (De Kimpe and Morel, 2000; Burghardt et al., 2015). The SUITMAs encompass a large diversity of soils with varying degrees of human influence depending on the history of their land use. Nowadays, inhabited areas face many issues mainly related to the increased population living in cities, the needs of food, energy and goods, and to the adaptation to climate change. In this context, the potential of SUITMAs to provide services such as support of green spaces and food production, regulation of the water cycle, or a reservoir of biodiversity should be considered better in land planning (Morel et al., 2015). Sustainable management of inhabited areas requires understanding of how human activities change soil properties and their ability to fulfill essential functions, and also to predict the evolution of soils in such environments. This chapter focuses on the study of SUITMAs as archives with the aim of improving the knowledge about human history, but also about the conditions and processes of soil evolution in inhabited areas.

Footprints of past human activities in SUITMAs

The succession of land use has left multiple traces in soils, which can be altered or erased over time. The investigation and reconstruction of the trajectories of these complex soils require multidisciplinary and multiscale approaches to decipher the successive mixed human and environmental contributions through time.

Fig. 1 Human–soil relationships in human-affected areas. Through history, human activities have successively disturbed the soils and the environmental conditions of soil formation. By modifying the soil characteristics (structure, constituents, properties), human activities alter their capacity to fulfill essential ecological functions and provide services necessary for the development of human societies in the short or long term.

Soils as archives of human–nature relations

Soils have the ability to record their past by storing information about factors and processes of formation. Several conceptual models have been established to explain the formation of natural soils. The classic factorial approach defines the state of the soil system with five factors: parent material, relief, climate, living organisms and time. Parent material and topography determine the initial state of the system, which evolves over time through the influence of climate and biological activity (Jenny, 1941). The process-based approach considers that the parent materials weather under the action of a combination of processes including additions, losses, transfers and transformations. These lead to the development of a soil profile and the differentiation of soil horizons with specific characteristics. The nature of the soil is governed by the relative importance and balance between the wide range of processes, which leave their imprint on soil characteristics (Simonson, 1959). The concept proposed by Rode in 1947 suggests that the repetition of incompletely closed cyclic processes involving mainly liquids, gases and biota (functioning processes) generates residual solid products that accumulate and differentiate in the long term (pedogenetic processes). The soil memory relies on the direct link between factors, functioning processes, pedogenetic processes and residual solid features at different scales (memory carriers), such as amorphous compounds, aggregates, horizons and profile (Targulian and Bronnikova, 2019).

Human activities have transformed soils and their conditions of formation and can have a long-term impact on soil composition and properties. Some soil features can be specific to human land use and related practices, like regular ploughing, fertilization, pollution or dumping of waste and construction debris. Thus, soils can contribute to store buried elements of human heritage, and can be considered as valuable recorders of human-induced changes of the environment. Human-modified soils have been proposed as markers of the start of the Anthropocene, which could be around 2000 BP when the terrestrial surface of the planet was noticeably modified by organized civilizations through the exploitation of natural resources, such as land cultivation, deforestation or mining (Certini and Scalenghe, 2011).

In that context, SUITMAs can be considered as archives of past urban, industrial or mining activities, and are of interest for educational and touristic purposes (Urbańska and Charzyński, 2021). Analyses of soil features can document the history of land use in correlation with other sources of historical information. In addition, such investigations of the past to reconstruct the trajectory of soils will enhance the understanding of the impact of land use practices on soils and will provide recommendations for future land management and planning (Riddle and Levin, 2017). In that way, SUITMAs can be helpful educational supports to raise awareness about the impact of human activities on soils and more generally on the environment, and to promote more sustainable management and protection of the limited soil resource.

Markers of human activities in SUITMAs

Depending on land use and the intensity of induced changes, human activities may alter the composition and properties of existing soils or greatly modify the organization of the soil profile, which may lead to the formation of new soils.

For example, SUITMAs may display disturbed profiles, with partial or complete disorganization of the horizons initially formed by natural soil development. Soil profiles can be modified by the truncation of upper layers, by mixing of the horizons during earthworks, by surface sealing or by burying of infrastructures or impermeable geomembranes in the soil (Fig. 2). Native soils can be buried under human-transported materials, either earthy materials brought from surrounding areas as backfill or human-made materials generated by urban, industrial or mining activities. Soils can also be intentionally amended or even constructed to fulfill specific functions, such as to support vegetation. Such soil constructions consist of mixed organic and mineral by-products from urban or industrial activities to obtain the required soil properties, which are deposited in layers to mimic natural soil horizons

Fig. 2 Possible human-induced changes of soil organization along the profiles of soils of urban, industrial, traffic, mining and military areas (SUITMAs).

Fig. 3 Example of urban soil with a large content of artifacts: (A) profile of a soil formed in loamy fill with construction debris in New York City (Laguardia series in the city-wide soil map completed by USDA-NRCS Soil Survey group; <http://websoilsurvey.sc.egov.usda.gov/App/HomePage.htm>), (B) distribution of the types of artifacts in the coarse fragments (> 2 mm) and (C) pictures of the main types of artifacts. This profile was described in Huot H, Joyner J, Córdoba A, et al. (2017) Characterizing urban soils in New York City: profile properties and bacterial communities. *Journal of Soils and Sediments* 17: 393-407.

(Séré et al., 2010). As a result, SUITMA profiles may display a complex polygenetic organization with the superimposition of layers reflecting the succession of human transformations. The burying by new inputs may inhibit evolution of the buried soil materials, leading to a 'book-like' type of memory, typical of sedimentary systems. When the human disturbances stop, the 'new' soil gradually evolves under the natural environmental factors with a 'palimpsest' type of memory (multiple records on the same 'page'), typical of natural soils. Thus, profiles of SUITMAs can record land use changes over time as well as the conditions of soil formation (Prokofeva and Poputnikov, 2010).

One of the main footprints of human activities in soils is the presence of artifacts, i.e. materials created or modified by industrial or artisanal manufacturing processes or brought to the surface by human activity from a depth where they were not influenced by soil-forming processes. Artifacts include construction debris and waste of human settlements, industrial waste, mine spoil, dredged sediments, excavated bedrocks and oil products (IUSS Working Group WRB, 2014). The presence of construction debris is common in urban soils because of long accumulation of debris from regular demolition and reconstruction of houses as well as destruction by wars or fire (Fig. 3). Construction debris was often disposed of at or near the site of demolition, so ancient cities are generally built on their own waste (De Kimpe and Morel, 2000).

At the end of the Second World War, many European cities lay in ruins. In Berlin, 75 million m³ of debris was deposited throughout the city. Part of the debris that was not reusable as building materials, was used as foundations or disposed of in heaps (up to 100 m in elevation) in public parks and the outskirts of the city, and were revegetated to create recreational areas. Soils developing on debris contain large amounts of coarse fragments (> 2 mm) and artifacts such as bricks, mortar, slag and ashes, metal and electrical scrap, which bear witness to the city's past. The nature and size of these anthropogenic components influence the soil physical, chemical and biological properties, and also the quality of water percolation. For instance, sulfates have been leached from WWII debris into ground water in Berlin (Wessolek et al., 2011).

In addition to the incorporation of human-made materials, atmospheric depositions from industrial activities and traffic or regular additions of amendments and gardening practices contribute to alter the soil geochemical composition. Consequently, phosphorus, metals like copper (Cu), zinc (Zn), cadmium (Cd) or lead (Pb), and also organic compounds resulting from combustion (black carbon) or from petroleum products are often enriched in SUITMAs. They are likely to contain large concentrations of potentially toxic compounds that need to be identified and monitored for their fate (De Kimpe and Morel, 2000). These soils can also be highly compacted due to earthworks and the use of heavy machinery.

Deciphering memory of past human activities in SUITMAs

The preservation of soil memory depends on the weathering conditions and the evolution of natural and anthropogenic soil-forming factors. Consequently, it is necessary to take a multiscale, multidisciplinary and multi-proxy approach to decipher

anthropogenic signatures and traces of pedogenic processes, and to establish hypotheses of reconstruction. In particular, documentation about the history of land use at sites studied and knowledge on artisanal and industrial processes used to produce materials present in the soils, are a useful complement to the soil analyses. This is illustrated through two examples of studies of soils as archives of past urban and industrial activities.

Urban soil stratification as record of the city history

Urban areas encompass a large diversity of soils, from soils which have preserved the characteristics of natural regional soils, for example in urban forests, to soils strongly transformed by successive human land uses (e.g. land clearance, cultivation, building and infrastructure construction, artisanal and industrial activities) during city development. In ancient towns, accumulation of anthropogenic wastes, partially transformed by pedogenic processes, has led to the formation of 'cultural layers' comprising the superimposition of weakly developed buried soils overlying the initial natural soils (Alexandrovskiy et al., 2012). Cultural layers are a source of historical information about city development and the interactions between humans and their environment (Alexandrovskaia and Alexandrovskiy, 2000).

The study of such urban soils benefits from an interdisciplinary approach linking archeology and geosciences. First, the organization of the soil and distribution of artifacts are observed at the meter scale in excavations. Stratigraphic units are delimited in the soil profile depending on the variation in characteristics of the materials (e.g. color, texture, presence of artifacts). The units are then sampled and characterized to obtain further information about the nature of the different inputs and processes of accumulation, erosion and transformation. Methods used to analyze urban strata include micromorphology, physicochemical analyses (e.g. particle size analysis, organic matter, nutrients, metals and carbonates), geophysics, quantitative and qualitative study of the artifacts (e.g. charcoal, pottery), and archeozoological and botanical investigations (phytoliths, pollen, seeds). Artifacts or organic compounds in the soil can be dated, for instance using radiocarbon analysis (Borderie et al., 2019).

In ancient European cities, urban strata often include thick poorly stratified layers of dark color and contain important artifacts. These urban 'Dark Earths' occur in a wide range of environmental and historical contexts, and recur between the strata of antiquity (before 4th century) and the Middle Ages (11th century) in northwestern Europe. Characteristics of such layers depend on the pedoclimatic context and the different inputs linked with the land uses. But they generally include significant concentrations of organic matter with a high C/N ratio due to the large presence of charcoal and organic fragments, thereby contributing to carbon storage in urban soils. The diversity of artifacts indicates the nature and origin of the inputs, such as building materials (mortar, bricks, tiles, plaster), domestic activities (manure, bones) or craft activities (ash, charcoal, slag, glass). Geochemically, Dark Earths often show an enrichment in phosphates related to the addition of manure, bones or ashes and in metals as a result of past or more recent polluting activities. They are likely to have neutral to alkaline pH with the presence of carbonated artifacts from construction materials. If these deposits show an apparent homogeneity at the macroscale, the study of micromorphological features gives valuable information about the processes of accumulation and transformation leading to the formation of Dark Earths (see example in Fig. 4). In particular, bioturbation contributes to homogenization of the deposits, which can also be due to mechanical soil cultivation. Percolation and waterlogging also affect mineral weathering and organic matter preservation in these soils. The main interpretations of the origin of Dark Earths included gardening practices, waste deposition or abandonment of some urban areas with subsequent development of vegetation and homogenization by strong biological activity. More recent investigations using a geoarcheological approach revealed that Dark Earths result from a complex combination of processes depending on environmental conditions and practices associated with the multiple uses of these urban spaces. In this way, these soils store information about the medieval conditions of life and their study contributes to a new perception of the urban spaces at this period (Borderie et al., 2019).

Soils of industrial brownfields as archives of past industrial activities

With the decline of heavy industry at the end of 20th century, some areas in industrialized countries include numerous 'brownfield' sites that were abandoned following the closure or even demolition of plants. Spontaneous vegetation growth has generally occurred on these sites, sometimes leading to the establishment of forested ecosystems. The rehabilitation of these sites depends on the site constraints (e.g. pollution, infrastructures, land pressure), regional redevelopment programs and stakeholders involved. Brownfields may have a heritage value which can be recognized and preserved. Analyses of their soils and of the artifacts they contain can complement the work of historians and archeologists about the history of these industrial sites (Urbańska and Charzyński, 2021). Documentation of the site history (e.g. aerial views, former maps, administrative documents) and information about the industrial processes are also useful for such sites for risk assessment and reconstruction of their trajectory of evolution.

Investigations of such sites need to combine observations at different scales (site, profile, microstructure) with soil and artifact analyses, including geochemical and mineralogical ones. The nature and distribution of major and trace elements, organic compounds and minerals can be used as tracers of industrial by-products and their subsequent changes in the soil. Enrichment or depletion in some elements compared to the regional background concentrations can reveal anthropogenic inputs and or activities. Molecular markers, based on the distribution of some classes of aliphatic, aromatic or polar compounds, can be used to distinguish natural or anthropogenic origin of soil organic matter and different sources of organic pollutants (e.g. combustion, petroleum products). The study of mineral phases together with knowledge about the industrial processes and conditions of formation and weathering of these minerals (e.g. temperature, pH, redox potential) helps to establish hypotheses about the origin and transformations of the minerals.

Fig. 4 Example of late medieval dark earth soil formation at the ancient convent garden in Lunéville (North-East France): dark earth (layers D and E) overlying a cultivated alluvial soil (layers A, B and C), based on description of the soil profile, the distribution of artifacts and micromorphological features observed in thin sections along the profile (1 to 11). Source: A. Gebhardt, French national institute for Preventive Archaeological Research INRAP.

As an example, a soil developed on a former settling pond storing blast furnace sludge from the iron industry was investigated using a multi-technique approach (Fig. 5; Huot et al., 2014a,b; 2015). It showed a particular geochemistry dominated by manganese (Mn), calcium (Ca), silicon (Si), iron (Fe), carbon (C) and aluminium (Al) with very large concentrations of potentially toxic metals such as Pb or Zn, which are related to composition of the raw materials and the enrichment of volatile elements in the blast furnace. From a mineralogical point of view, some phases are inherited from the raw material used in the blast furnace, such as Fe oxides from the iron ore. Other phases have been more or less (trans)formed in the blast furnace under high temperature, such as the formation of spherical aluminosilicate glass. Their weathering into poorly crystalline aluminosilicates or the precipitation of secondary calcium carbonates at greater soil depth indicate mineral (trans)formations under the influence of environmental factors in the settling pond. The molecular markers indicated organic compounds of vegetal origin in the surface horizon and of anthropogenic origin in the underlying layers with a signature of oil products and a contribution of combustion processes. The compounds inherited from the iron-making process are particularly well preserved in the soil, probably in relation to the soil mineralogy and physicochemical properties. This soil can be considered an archive of past industrial activities (Huot et al., 2014b). The study of micromorphological features revealed traces of physical, chemical and biological processes, such as the presence of cracks due to wetting–drying cycles, the precipitation of manganic coatings in the cracks related to changes in redox potential or the development of organo–mineral associations at the surface under the action of soil fauna (Huot et al., 2015; Fig. 5). Such studies are useful to propose scenarios of evolution, and to assess the risks of dispersion of contaminants in these industrial soils.

Human-induced modifications on factors of evolution

The preservation of these soils and materials they contain as archives of past human activities will depend on the context of their evolution. In human-affected areas, soils undergo the effects of both natural and anthropogenic factors, creating unique conditions of soil evolution. Human activity can be integrated in the soil-forming factor ‘organisms’, but given the intensity of human-induced soil changes in the Anthropocene, it has been proposed to consider humans as a sixth factor of soil formation (Dudal, 2005). Human impact can be direct or indirect through the modifications of the five natural soil-forming factors.

Fig. 5 Multi-technique approach for the reconstruction of the formation of a soil developing on a former settling pond of an iron industry under a forest cover by combining observations and analyses at different scales of the soil profile as tracers of the origin and the evolution of the materials: (A) micromorphological features, (B) molecular markers of the sources of organic matter, (C) distribution of the contents of major and trace elements along the profile and (D) nature and weathering of mineral phases.

Parent materials

The role of the parent materials is crucial in soil formation, especially during the early stages. The degree and rate of weathering depends on the nature and reactivity of parent materials and the environmental conditions. As shown above, SUITMAs encompass soils with varying degrees of human influence on the nature and mode of deposition of the parent materials. As a result, these soils may develop on materials with specific mixtures of natural and anthropogenic constituents, quite different from the composition of natural bedrocks or sediments. The persistence of artifacts and stratigraphic evidence of human activities depends on both the soil environment, in which they are buried, and on the nature of the constituents and conditions of their production. For instance, the nature of the clay and firing temperature influence the robustness of ceramics in soils (Kibblewhite et al., 2015). The susceptibility of anthropogenic materials to weathering is also affected by some of their properties, such as the granulometry, porosity, specific surface area, molecular structure of organic compounds or the degree of crystallinity of minerals. Fragmentation during the manufacturing process or their deposition may favor the weathering of man-made or -transported materials. The main soil properties influencing the dissolution or degradation of archeological artifacts include hydrology which determines the levels of dissolved oxygen, soil acidity or alkalinity, concentrations of solutes and of dissolved organic matter in soil solution, and soil stiffness (measure of resistance to deformation) that condition the physical protection of brittle artifacts. Stratigraphic evidence is better preserved in soils receiving regular inputs of materials, subjected to little or no erosion, with wet anaerobic conditions or with low bioturbation (Huot et al., 2015; Kibblewhite et al., 2015). Human-induced modifications on the exposure of the materials (e.g. burying, sealing) and the soil's environmental conditions (e.g. pollution, acid rain, use of deicing salts, water table fluctuations, fertilizer application) can favor or limit weathering of the parent materials. For example, the study of buried artifacts after one century in an urban soil showed that the stability of artifacts to weathering (glass > bone > mortar > plaster > paint) accorded with the solubility products of the main mineral constituents of these artifacts. Their good state of preservation could be due to carbonates in the soil environment and compaction limiting the fluxes of water and air into and within the soil. The activity of earthworms can help to preserve artifacts by burying them beneath the layer created by casting activity, but could also have the opposite effect by creating deep vertical burrows that increase air and water circulation in the soil. Interactions between weathering processes of diverse artifacts may also influence the rates of weathering. For instance, the leaching of phosphates from bones or carbonates from mortar and the precipitation of protective coatings contribute to the preservation of iron artifacts (Howard et al., 2015).

Topography and hydrology

Human activities can greatly disturb the topography and hydrology. Earthworks related to urban management, mining and quarrying or the effects of bombing in war zones strongly modify the local topography and generate typical anthropogenic landforms. The U.S. Soil Taxonomy distinguishes (i) constructional anthropogenic landforms or microfeatures on land that has been elevated or raised by human activity (e.g. burial mounds, dumps, spoil banks from dredging, earthworks, sanitary landfills, spoil banks, reclaimed land, terraces, embankments) and (ii) destructional anthropogenic landforms or microfeatures on land that has been cut or lowered without being backfilled (e.g. cuts, dredged channels, earthworks, leveled land, open pit mines, quarries, ditches, furrows, terraces, impact craters) (Riddle and Levin, 2017). Human-modified landscapes may have steep slopes that are subjected to severe erosion, runoff and landslides. Remediation of these sites can encompass geomorphology in the design to promote soil formation and vegetation development.

These modifications of the topography have impacts on the groundwater level. In addition, surface and subsurface sealing, buried infrastructures or drainage alter the interlinking between soils and the water regime in human-affected areas (Burghardt, 1994). For instance, the groundwater table rose in urban soils in Moscow because of the accumulation of technogenic materials and gradual leveling of the topography (Alexandrovskaya and Alexandrovskiy, 2000). Furthermore, soils with geomembranes or on green roofs or walls are disconnected from the groundwater.

Water balance in urban and traffic areas shows considerable spatial variation with areas of extreme infiltration or evapotranspiration adjacent to areas with almost no infiltration or evapotranspiration (Burghardt, 1994). For example, roadside soils have a high rate of infiltration compared to those further from the road because of runoff from the road (Wessolek et al., 2011).

Climate

As for natural soils, the climate, mainly the dynamics of precipitation, temperature, and freeze–thaw cycles, is a factor in the evolution of SUITMAs. The climatic conditions also influence the development of vegetation and soil biota, which are crucial soil-forming factors. For instance, a study of soils developed on the tailings of coal mines of different ages from humid to arid conditions in Siberia showed the formation of profiles specific to the different climatic zones (Sokolov et al., 2015).

Human activities affect the climate globally and locally. Urban areas usually have higher temperatures than the surrounding rural areas, especially at night, thereby forming urban heat islands. Climate change might induce significant modifications to temperature and precipitation regimes, with potential augmentation of the intensity and frequency of extreme weather events, such as droughts, heavy rains, cyclones or heatwaves. This will affect the evolution of all soils around the world, including SUITMAs and the anthropogenic materials they contain.

In human-affected areas, modification of the interface between the soil and atmosphere, and artificial hydrologic management moderate the direct effect of natural climatic conditions on SUITMAs. Kodešová et al. (2014) showed that the nature of the soil cover (e.g. sand, bark chips, gravel, concrete paving) influences water and heat regimes in urban soil profiles. Soil sealing is common in urban and traffic areas leading in general to higher soil temperatures, limited water infiltration and gas diffusion depending on the degree of sealing (Scalenghe and Marsan, 2009). Moreover, structural modifications of soils (e.g. compaction, lithological disturbances, presence of artifacts) as well as the burying of pipes may modify both heat and water flow within such soil profiles. Soils covering capped landfills may have higher temperatures due to microbial activity in the refuse layer. Effluxes of gases (mainly methane (CH₄) and carbon dioxide (CO₂)) through cracks in the capping system may change the soil atmosphere and create anaerobiosis (Handel et al., 1997). Regarding water management, irrigation can create similar soil moisture conditions in different climatic zones in highly managed soils, such as golf courses (Obear et al., 2014).

Organisms

Plants, soil microorganisms and fauna play a major role in soil evolution and functioning of SUITMAs as in more natural soils. Human activities modify the habitat of organisms through the alteration of chemical and physical soil properties or through management of the vegetation cover. Consequently, the abundance, diversity, structure and activity of biological communities may be different in SUITMAs, thereby affecting soil development.

Some SUITMAs have unfavorable chemical and physical conditions (e.g. nutrient deficiency, water stress, salinity, extreme pH, compaction, large contents of coarse fragments) and/or problems of toxicity depending on the availability of contaminants they contain, which inhibit organism growth and activities. Soil sealing reduces soil biodiversity. Microbial biomass is reduced under impervious surfaces due to low carbon concentrations, moisture and aeration (Piotrowska-Długosz and Charzyński, 2015). Plant root development can be constrained by debris or compacted layers which act as a mechanical barrier. Urban trees generally have restricted volumes of soil to grow in with limited water and nutrient storage, which reduce the extension of their root system (De Kimpe and Morel, 2000). In cities, habitats are fragmented by the construction of buildings and roads, and green areas are dominated by exogenous ornamental plant species. Consequently, urbanization may lead to biological homogenization (Scalenghe and Marsan, 2009).

Recent studies, however, have revealed unexpected high levels of soil biodiversity in some SUITMAs. For instance, based on communities of soil microarthropods, the biological quality of urban garden soils and industrial brownfields was similar to that of forest soils and higher than that of agricultural soils; this contradicts what might be expected from the physicochemical soil properties (Joimel et al., 2017). Important factors for the development of soil biota are the diversity and density of plant cover, the quantity and quality of organic matter including exogenous organic inputs, and the intensity of land management and frequency of human interventions. The spatial heterogeneities of substrates and of physical and chemical properties, and changes in the microtopography create a mosaic of microhabitats with varying microclimates (e.g. temperature, moisture) in SUITMAs, which favors high biodiversity (Auclerc, 2017). Organisms may take advantage of these heterogeneities to develop in preferential areas like depressions or cracks. For example, in well-drained soils developing on debris, deep rooting to reach layers with more water supply depends on the size and compaction of the stones. A high density of roots and root hairs has been observed on bricks, probably showing their ability to use the water and nutrients stored in them (Nehls et al., 2013; Wessolek et al., 2011).

Regarding the dynamics with time, primary successions can occur on bare substrates, such as mine tailings, industrial by-products or abandoned infrastructure, whereas secondary successions take place in ecosystems after disturbances, such as compaction, erosion, contamination. Pioneer species on such bare substrates modify the habitat for other species. Remediation practices (e.g. leveling, addition of amendment, planting) may help to improve conditions for the development of organisms and to accelerate processes of natural succession. However, remediation techniques could also result in uniform conditions, thereby decreasing the diversity of such ecosystems (Auclerc, 2017).

All these abiotic and biotic constraints on biological communities in SUITMAs may generate specific structures of communities compared with native soils. For example, in temperate climates, a lack of earthworms was observed in various SUITMAs because of sharp artifacts, and unfavorable physical properties (texture, moisture) or toxicity (e.g. Burghardt, 1994).

Time

Soil formation depends on the time from deposition of the parent materials (time zero). In human-influenced areas, however, the period of pedogenesis is related to land use history and degree of human disturbances. Soils subjected to few or indirect influences of human activities (pseudonatural soils) can be as old as surrounding natural soils. However, the input of natural or anthropogenic materials or strong alterations of naturally developed soil profiles may create the conditions to reset soil development to a new time zero. Consequently, soils markedly affected by human activities are relatively young, from several years or decades to thousands of years in ancient cities or mines. The evolution of these soils is controlled by the succession of human activities, which is typical for old settlement places (Alexandrovskiy et al., 2012).

In summary, SUITMAS develop under varying conditions from pseudonatural to highly disturbed and managed environments. Human activities can modify each of the five soil-forming factors and their interactions. This may lead to specific conditions of soil evolution in human-influenced areas (Fig. 6).

Fig. 6 Potential conditions of soil evolution in human-affected areas. Transport, mixing and incorporation of substrates result in a unique mixture of diverse constituents from both natural and anthropic origins. Alterations of local topography and hydrology, modifications of plant and soil cover and water management modulate the dependence of soils on the bioclimatic factors. These soils are characterized by spatial heterogeneities related to the deposition of parent materials, alteration of local topography and development of organisms in preferential areas. Soil development is controlled by the pace and degree of human disturbances, which can reset the pedogenesis.

Evolution of SUITMAs

In view of the conditions for the evolution of SUITMAs, the question of their long-term evolution arises. What are the consequences of human-induced changes of factors on the soil-forming processes? How can the evolution of such soils and their anthropogenic materials be predicted?

Main soil-forming processes observed in SUITMAs

Based on studies of the pedogenesis of SUITMAs, a list of the main processes of accumulation, transfer and transformation reported in the literature is given below (Huot et al., 2015).

Accumulation and transformation of organic matter

The accumulation of organic matter (OM) at the surface is one of the most commonly reported soil-forming processes in all types of SUITMAs, except for sealed ones. It mainly relates to vegetation and biological activity, and exogenous organic inputs. In urban soils developing on debris, organic matter accumulates over time at an increasing rate initially before a steady state is reached (Wessolek et al., 2011). It can be enhanced by inputs of organic amendments within the scope of remediation of brownfields or mine tailings, or by horticultural and gardening practices (e.g. Howard et al., 2015). In SUITMAs, organic matter may accumulate in deeper layers with the input of organic waste and or by burying the organic horizons of native soils, as in urban Dark Earths. Soil sealing decreases organic matter and nutrient concentrations compared to open sites, because of the removal of topsoil during construction and the absence of organic debris inputs through the impervious covers (Kida and Kawahigashi, 2015).

Degradation, transformations and migration of organic substances depend on many biotic and abiotic properties, such as the nature and recalcitrance of the organic compounds, the microbial and faunal communities and the soil conditions (e.g. pH, moisture, mineralogy, porosity). For example, OM degradation may be retarded in some SUITMAs due to waterlogged conditions (Alexandrovskiy et al., 2012) or physical protection in small pores, and stabilization by interaction with reactive mineral surfaces (Huot et al., 2014b). Soil sealing induces a decrease in microbial biomass and enzyme activities, contributing to a decrease in OM turnover (Piotrowska-Długosz and Charzyński, 2015). The lack of earthworms observed in different types of SUITMAs may contribute to limiting incorporation and mixing of OM in the soil.

Mineral transformations

The evolution of SUITMAs is marked by the weathering and neoformation of minerals, mainly controlled by changes in pH and redox conditions in relation to climatic and biologic factors.

Oxidation of sulfides and the subsequent formation of sulfates and iron oxides commonly occur when materials brought to the surface by human activities from reducing environments (e.g. sulfide-containing mine tailings, dredged sediments, excavated rocks) are in contact with oxygen and water, and subjected to the action of some microorganisms. This reaction releases sulfuric acid, leading to the formation of acid mine drainage rich in potentially toxic metals. The degree of sulfide weathering increases with time and can be an indicator of material transformations (Uzarowicz and Skiba, 2011).

Changes in redox conditions in relation to wetting-drying cycles trigger the dissolution, translocation and precipitation of Fe and Mn oxides in soils formed in iron-rich materials (e.g. iron industry by-products, ferrous artifacts) or fertilized with Fe

compounds. These processes lead to the formation of Fe—Mn concretions (Sokolov et al., 2015), coatings in cracks and on mineral surfaces (Huot et al., 2014a), crusts associated with iron artifacts (Howard et al., 2015) or cemented layers (Obear et al., 2014).

Changes in pH are also an important driver of mineralogical modifications. Acidification resulting from the decomposition of organic matter, percolation of water or sulfide oxidation promote the dissolution and leaching of carbonates from calcareous anthropogenic materials. This may cause the alkalization of buried natural acidic soils, such as volcanic soils under road sub-base layers (Kida and Kawahigashi, 2015) or podzolic soils under historical deposits of construction debris (Alexandrovskiy et al., 2012). Precipitation of secondary calcite as crusts, coatings in cracks or nodules has been observed in various SUTIMAs formed in industrial by-products, mine dumps or construction debris (e.g. Huot et al., 2015; Howard et al., 2015). Acid reactions in anthropogenic materials may also promote the weathering of primary silicates into clay minerals (Uzarowicz and Skiba, 2011). Alkaline pH values are conducive to the weathering of aluminosilicate glass resulting from industrial processes (Huot et al., 2015).

Transfers of soluble compounds and particles

The leaching of soluble compounds (sulfates, carbonates or chlorides) is often reported in various SUTIMAs developing on anthropogenic materials, such as construction debris or industrial by-products. For example, the leaching of sulfates from WWII debris has led to contamination of the groundwater of Berlin (Wessolek et al., 2011). Even under asphalt surfaces, water infiltration through cracks enables dissolution of calcium cations from subbase materials and accumulation of calcium carbonates in deeper horizons (Kida and Kawahigashi, 2015). In addition, translocation of fine particles that filled cracks was observed in some SUTIMAs, for instance in urban soils from the construction debris deposits into the underlying soil in cracks (Alexandrovskiy et al., 2012).

Development of soil structure

The development of soil structure in SUTIMAs is mainly controlled by the inputs of organic matter and the activity of roots, microorganisms and soil fauna, but also depends on the deposition of parent materials and particle mixing related to human activities. The formation of granular structure under the activity of roots and fauna has been observed in different anthropogenic substrates. Aggregates involving anthropogenic mineral and organic components, such as hydrocarbons, green waste or sewage sludge, has been reported in brownfield soils or in constructed soils (e.g. Séré et al., 2010).

Differentiation of soil horizons

Profiles of SUTIMAs are generally little differentiated because of their young age and their organization is marked by the deposition of materials and traces of human intervention. However, a rapid morphological differentiation in the layers occurred in a soil constructed by the deposition of different layers of anthropogenic materials (Séré et al., 2010). Accumulation of organic matter at the surface contributes to the formation of organic (O) and organo–mineral (A) horizons with increasing thickness over time (Bini and Gaballo, 2006). The (O) –A–C profiles can evolve towards (O) –A–B–C profiles, with the development of a cambic horizon or accumulations in layers at depth resulting from the leaching and precipitation of sulfates, carbonates (e.g. Howard et al., 2015) or Fe oxides (Obear et al., 2014).

Specific pedogenetic trends in SUTIMAs

Most of the pedogenetic processes observed in SUTIMAs seem similar to those in soils in natural environments (Huot et al., 2015). However, specific human-induced conditions of evolution may generate some particular features in the combination, localization and temporality of the processes in SUTIMAs.

Concomitant processes governing the pedogenesis of different types of natural soils have been observed in some SUTIMAs, probably related to the diversity of their constituents. For instance, the study of soil developing on by-products of the iron industry; Fig. 5 shows the weathering of glass and neoformation of poorly ordered aluminosilicates as in volcanic soils, segregation of Fe and Mn as in hydromorphic soils and migration and precipitation of carbonates as in calcareous soils (Huot et al., 2015). Processes which are usually typical of different climatic regions may also occur. For example, the leaching of sulfates from construction debris or industrial by-products was observed in temperate humid regions (Séré et al., 2010; Wessolek et al., 2011), whereas this process is generally more often encountered in arid regions. This could result from the presence of anthropogenic materials with a distinctive composition from the natural materials in this climatic region. Soil sealing and management may also reduce the dependence of the soil-forming processes on climatic condition. For instance, Fe-cemented layers observed in golf course soils may develop independently from the climate because all golf course soils are fertilized with Fe, engineered with textural discontinuities and irrigated to provide similar soil moisture conditions (Obear et al., 2014).

Frequently, SUTIMAs display considerable spatial and vertical variation from materials deposited and human disturbances. This can favor local processes, such as preferential precipitation of minerals in cracks (Huot et al., 2014a) and or at a textural discontinuity (Obear et al., 2014), and preferential biological development, and associated processes like rhizosphere effects. This may lead to variable rates and orientations of pedogenesis over a short distance (Bini and Gaballo, 2006).

Rapid and intense weathering has been often reported in the early stages of pedogenesis of SUTIMAs. This could be attributed to the disequilibrium between anthropogenic materials and environmental conditions (Séré et al., 2010). By contrast, soil development can be hindered by restricted biological activity, sealing or recalcitrance of some anthropogenic materials. As in alluvial soils, the degree of development of soils in human-influenced areas depends on the rate of deposition of materials and human

Fig. 7 Specific pedogenic trends and hypotheses of evolution of SUITMAs. The diversity of constituents, large spatial heterogeneity, and development constrained by the pace of human operations may create conditions for a combination of pedogenetic processes in SUITMAs, which rarely coexist in natural soils developing under the same climatic conditions. These trends raise several questions about the possible evolution of SUITMAs, including the direction of pedogenesis, diversity or polycyclic evolution of such soils. Adapted from Huot H, Simonnot M-O, and Morel JL (2015) Pedogenetic trends in soils formed in technogenic parent materials. *Soil Science* 180: 182–192.

disturbances. Urban soils of Moscow contain thin organic layers corresponding to the development of soils under herbaceous vegetation and trees when the time span between consecutive inputs of construction debris was greater than 10 or 20 years (Alexandrovskaya and Alexandrovskiy, 2000). The new top layers may interrupt pedogenesis and preserve the features acquired during previous surface weathering in buried layers.

In summary, the diversity of constituents, relative independence from the bioclimatic factor, the spatial heterogeneity, and soil development constrained by the pace of human interventions may create conditions for a combination of pedogenetic processes in SUITMAs, which rarely coexist in natural soils developing under the same climatic conditions (Fig. 7; Huot et al., 2015).

Prediction of the evolution of SUITMAs

Based on the specific trends in the pedogenesis of human-influenced areas, several questions arise about the possible evolution of SUITMAs (Fig. 7). The large diversity of SUITMAs and their relatively young age hamper the prediction of their long-term evolution. Modeling of pedogenesis can be a predictive tool to determine the partial influence of the main factors controlling soil development. However, quantitative pedogenesis models adapted to human-affected soils still need to be developed. Integrating the human influence into existing pedogenetic models requires consideration of the presence and type of anthropogenic materials and the considerable variation in soil physico-chemical properties, spatial heterogeneities, and temporal changes at different scales (Legu  dois et al., 2016). In this respect, it seems essential to improve the quantification of soil-forming processes, together with the monitoring and simulation of pedogenesis under the influence of human activities. The investigation of older SUITMAs and reconstruction of their past evolution with the history of the sites can help us to understand human-induced changes on the paths of evolution.

Direction of the pedogenesis

The potential combinations of soil-forming processes in anthropogenic soils raise the question as to whether the development of such soils will be controlled by the interactions between these processes or by a dominant process that will determine the direction of pedogenesis and the type of soil towards which these systems will evolve. If short-term laboratory experiments can be used to simulate the weathering processes of anthropogenic materials under various controlled conditions, they should be complemented by long-term field observations of SUITMAs and analogous natural soils (Scholtus et al., 2014). For soils developing on excavated geological materials, the comparison with natural soils formed on outcrops of similar parent materials under similar climatic conditions could be of value to predict long-term evolution. For example, the study of a young soil formed on excavated calcareous clayey rock, and of agricultural and forest soils formed on similar parent materials has shown that development of the anthropogenic soil will be controlled in the short term by the leaching of salts and accumulation of organic matter, and in the long term by decarbonization and brunification processes. This will lead to the formation of Cambisols (Scholtus et al., 2014). For soils developing in human-made materials, it can be assumed that their influence on pedogenesis will decrease with time, depending on the nature and quantity of anthropogenic materials and the conditions of weathering. Some predictions have been made by analogy with regional soils formed in natural parent materials with similar properties to the anthropogenic ones and under the same climatic conditions (e.g. S  r   et al., 2010; Sokolov et al., 2015). Sequences of evolution have been proposed from the study of

soils developing on anthropogenic materials abandoned at different times (chronosequences) over centuries or even millennia compared with adjacent natural soils (Bini and Gaballo, 2006).

Spatial variation and soil diversity

Spatial variation in the composition of parent materials and/or of hydrology, and the presence of hotspots of biological activity may generate the potential for distinct soils to develop over short distances in human-influenced areas. For instance, soil sealing can lead to the formation of soils that are distinct from the native and surrounding soils solely by limiting some processes, such as OM accumulation (Kida and Kawahigashi, 2015). This could increase pedodiversity at the scale of one industrial or mining site or in a city. However, the relative homogenization of anthropogenic processes across the world could also lead to a reduction of soil diversity in human-affected areas compared to natural sites (Burghardt, 1994). Human activities could contribute to the convergence of soil properties depending on the land use with actions taken to limit the constraints related to environmental factors, such as irrigation, leveling of the topography, use of pesticides, or fertilization. This hypothesis of convergence of urban ecosystems has been evaluated for some soil chemical properties in five cities in the world across four biomes. It showed that some urban soil characteristics such as organic C and N concentrations converged across these cities under the influence of soil management practices. But other properties (e.g. phosphorus (P) and potassium (K) concentrations) associated with local pedogenic factors such as parent materials were distinct depending on the cities (Pouyat et al., 2015). From a historic point of view, the investigation of cultural layers in ancient cities of Russia in boreal and steppe zones showed a zonality of the urban deposits related to changes in the bioclimatic conditions and associated processes, but also related to the nature of the anthropogenic inputs; a more organic character in forest zones and a more mineral character in the steppe zones. However, the evolution of construction techniques in Russian cities in the last centuries has led to more similar deposits of construction debris between cities that are independent of the bioclimatic area (Alexandrovskiy et al., 2012). Such results take us to a new hypothesis of a greater similarity between SUITMAs with the same land use from various geographic positions than between them and surrounding natural soils.

Temporal discontinuities

The SUITMAs are also likely to be polycyclic from the successive inputs of materials, leading to the development of incipient soils and burying of the native soils (De Kimpe and Morel, 2000; Bini and Gaballo, 2006). The superimposition of distinct types of materials could lead to separate weathering trajectories in successive incipient soils. However, the evolution of anthropogenic materials and the underlying buried soils may also be interconnected. For instance, the leaching of carbonates from the layers of construction debris may cause the alkalization of buried native acidic soil (Alexandrovskiy et al., 2012). The development of anthropogenic soils is likely to be marked by thresholds in response to changes of external natural or anthropogenic factors or intrinsic changes of soil properties. Understanding and modeling their evolution requires integration of the periodic changes in the short-term and changes in trend in the long-term. The decadal scale is appropriate to monitor human-induced changes of various soil properties (Legu  dois et al., 2016). Monitoring data at this time scale is necessary to detect the transition points in the soil's evolution trajectory and to improve our knowledge about rates of soil-forming processes in SUITMAs, especially by chronosequence studies (Bini and Gaballo, 2006).

Concluding remarks

The soils and human-made or human-transported materials they contain contribute to information stored about past human activities and the development of inhabited areas. In this way, their investigation constitutes a valuable complement to historical and archeological studies. Conversely, the characterization of these complex soils and the reconstruction of their formation requires a multidisciplinary approach that couples history, archeology and geosciences. Such studies provide information about the fate of human-made materials and potentially toxic compounds, and the possible paths of soil development. Sustainable management of inhabited areas requires us to consider the potential of soils in land planning. The challenge is to provide indicators of soil quality for land-use planning. In such areas, it can be assumed that the quality of soils depends on the historical evolution of the land uses it underwent. Based on this assumption, mapping of the land-use history and associated soil disturbances can be a valuable tool to help decision making about the preservation of areas of interest for green spaces, urban agriculture or biodiversity (Franck-N  el et al., 2015). Future research is needed to link history of land uses and soil use potential better. In addition, longer-term monitoring of these soils and further characterization of the artifacts and their reactivity would improve the prediction of their evolution in the context of global change. Thus, the soils of highly human-influenced areas open up a new path for soil science, i.e. prediction of their pedogenesis, which is essential for the sustainable management of urban ecosystems, based on an in-depth analysis of their past.

Abstract

The pedosphere and biosphere together, despite their marked differences, form the skin of the Earth's terrestrial ecosystems. The ecozonal concept is one of the first concepts to enable classification of both soils and the biosphere. Climatic factors are the main trigger that creates the differences within soils or soil types, within ecosystem sub-types, and between both. This chapter provides a short introduction to the chapters with a special focus on soils and soil types that follow a zonal concept, but also on soils which follow the law of exception, both are within the Pedology Section of the second edition of the Encyclopedia of Soils in the Environment.

Key points

- Zonal concept of soil classification
- Regional climate as main trigger of soil formation
- Impact of environmental fluctuations
- Azonal and intrazonal soils

Soils and Ecozones

The idea and concept of classification and mapping of soils goes back to the famous Russian Soil Geographer Vasily Dokuchaev. He first introduced the classification of soils in their natural environment based on his research and geographical observations of specific soil types and sequences of soil horizons that dominate in specific climatic areas. Typical examples are permafrost affected soils and patterned ground (Gelisols, Cryosols) in polar and subpolar areas, or a dominance of Podzols (IUSS Working Group, WRB, 2022)/Spodosols (Soil Survey Staff, Soil Taxonomy, 1999) with their specific sequence of eluvial and illuvial horizons in the boreal ecozone, or soils of steppe ecosystems (Fig. 1), or soils of the Ferralsol- and Plinthosol-type in tropical environments with intensive chemical weathering (Fig. 2). Fig. 1 is a Chernozem (WRB)/Mollisol (ST) from northeastern Romania near Scânteia developed in eolian deposits of Pleistocene origin, and Fig. 2 shows an intensively weathered Ferralsol/Oxisol site from limestone weathering in Northeastern Thailand. Dokuchaev's great advantage was the existence of the sequence of almost all ecozones in Russia from subtropical climatic conditions in the south through the dry mid-latitude ecosystems to cold environments north of the Arctic Circle. He identified specific climatic and geographic patterns as the most important driving factors of soil formation, i.e. mean annual temperature and seasonal to daily temperature variations, or the pattern of distribution of precipitation from dry to wet with or without a distinct rainy season. In combination with oxygen, temperature and water (precipitation) are the catalysts of weathering and soil formation and are independent of the influence of other soil forming factors. These are important not only for recent processes of soil formation, but also for paleosols, which provide information about past environmental fluctuations (Fig. 3).

With an increasing interest in soil properties and processes, researchers have recognized that zonal concepts do not work at sites dominated by factors other than climate.

Azonal soils

Azonal soils are young soils with only the initial stages of soil development and weak profile differentiation. Those soils cannot be assigned directly to a specific climate zone and might be found almost everywhere. They are typical for lowlands near rivers characterized by periodic or episodic flood events (alluvial soils; Fig. 4), and for morphologically or tectonically active mountainous landscapes (Zink, 2015; Leptosols/Entisols).

Fig. 4 An episodically flooded Fluvisol on top of the lowest terrace of the Seti Khola near Puranchaur, Central Nepal. The bedding indicates the flood events with subsequent initial soil formation. Photograph by R. Bäumler.

Intrazonal soils

Intrazonal soils are characterized by the dominance of factors other than climate with respect to soil formation, like parent material (including organogenic material), hydric conditions, or anthropogenic soils. Typical soil representatives are Gleysols (WRB) or Stagnosols (WRB), Andosols (WRB)/Andisols (ST; Fig. 5), Vertisols (WRB and ST), Terraes calcis, Histosols (WRB and ST), and Anthrosols (WRB) with or without technogenic matter like Technosols (WRB), Terra preta (pretil horizon; WRB), Hortisols (hortic horizon; WRB), soil formation after mining activities or in disposed waste (Howard, 2021; Zech et al., 2022).

Concluding remarks

Deep understanding of soils involves knowledge of its factors of formation and surrounding disciplines, e.g. geology or lithology, geomorphology, climatology or atmospheric science, hydrology or the hydrosphere, flora and fauna or biosphere, and their mutual

Fig. 5 Histric Andosol/Andisol near Gunnarsholt, S-Iceland. Photograph by R. Bäumler.

interactions. Soil knowledge is the key to understanding environmental interdependency, resilience and protection in our fast-changing environment.

Soils no longer seem to be in balance with their biotic and abiotic natural surrounding conditions. Soil degradation by erosion, deforestation, desertification, sealing, soil compaction, misuse of pesticides, such as the neonicotinoids, are some of the problems we are confronted with. The protection of soils, one of our essential natural resources, should be one of our most important challenges in the 21st Century.

Zonal concepts have their justification (Schultz, 2005). Nevertheless, scientific concepts such as the ecozonal concept of soil classification have to be questioned at all times. Ecosystems are open dynamic systems characterized by fluxes of matter and energy. This will consequently lead to blurring of the effects and fluent transitions in combination with small-scale three-dimensional diversity (Mikhailova et al., 2021). This ultimately leads to some defining questions. For example, how can boundaries be defined between adjacent ecozones, or within altitudinal gradients in high mountain areas? Some boundaries such as terrestrial–semi-terrestrial or terrestrial–marine are not in accord with a climate-based ecozonal concept. Is a zonal concept of soil classification or soil formation a congruent synthesis of climate, soils and vegetation? Are ecozones a conceptual abstraction only – or based on natural constants? How should relict properties be embedded? For example are permafrost soils always part of the boreal ecozone? Is the human influence in the Anthropocene part of a natural causal network (Amundson, 2021)?

Abstract

Cold region soils are increasingly impacted by anthropogenic activities and climatic change. Despite their cold character, these unique soils are highly dynamic. Low temperatures depress but do not stop biochemical reactions. This results in high rates of carbon accumulation, and slow but significant chemical modification. Volumetric expansion and contraction due to water movement and phase change occurs in both permafrost and non-permafrost-affected soils, and dramatically affects their morphological, physical and chemical properties. Conserving and managing cold region soils sustainably depends on understanding their distribution, properties, and the unique set of physical and biochemical processes that occur in them.

Key points

- Cold region soils are physically and biochemically dynamic.
- Cold region soils are influenced by the presence or absence of permafrost, water movement, ice formation, redoximorphic processes, cryoturbation, and patterned ground.
- These dynamic aspects of soils in cold regions make them susceptible to climatic, environmental, and anthropogenic disturbances.

Introduction

The soils of cold regions are widely distributed and highly unique. Cold region soils may or may not be permafrost-affected, but permafrost-affected soils occur exclusively in cold regions. One of the major physical processes occurring in both permafrost and non-permafrost-affected cold region soils is volumetric expansion and contraction resulting from phase changes of water. Liquid water exists even in soils below 0 °C because of freezing point depression. This water can move towards the freezing front, dramatically influencing ground ice content and morphology as well as the formation of soil structure. The ubiquitous low temperature in cold regions slows the rates of biochemical reactions, which accounts for high rates of soil carbon accumulation

in these regions. However, microbial decomposition of organic matter does still occur, and biotic and abiotic reactions can result in significant modifications to soil parent materials over time. Where permafrost persists, the morphology and properties of cold region soils are extremely heterogeneous, influenced by the movement of soil materials due to freeze-thaw processes (cryoturbation) and linked closely to patterned ground formation. As cold regions continue to experience environmental change and pressures from development on a global scale, understanding the processes that occur in cold region soils and the effect that these factors have on their morphology and properties has never been more important.

Definition and distribution of cold region soils

Soil temperature and moisture regimes

Cold region soils can be defined as soils formed in areas with a mean annual soil temperature (MAST) of less than 8 °C (at 50 cm below the soil surface or at the top of a root limiting layer) and having soil formation controlled at least in part by cryogenesis or cryogenic processes, the physical, biological, and chemical processes that occur during freezing and thawing. This definition of cold region soils corresponds to the frigid, cryic (MAST between 0 °C and 8 °C) and gelic (MAST less than 1 °C or 0 °C) soil temperature regimes (STRs) in US Soil Taxonomy (Soil Survey Staff, 2014). The gelic STR includes the subgelic (MAST of 1 °C to −4 °C), pergelic (MAST of −4 °C to −10 °C), and hypergelic (MAST less than −10 °C) soil temperature classes (Soil Survey Staff, 2014) (Fig. 1). Despite their unifying cold character, these soils experience a wide range of annual temperatures and even wider ranges of annual soil moisture balance. Soil moisture regime varies significantly in cold regions, ranging from arid conditions to humid or aquic (saturated) conditions. These soil temperature and moisture regimes and classes correspond broadly to boreal or subarctic (Dfc, Dwc), arctic (Dfd, Dwd), and high arctic or polar (ET, EF) Köppen climate zones.

Distribution of cold region soils

The northern circumpolar region (north of 45°N latitude) contains the largest extent of cold soils in the world, upwards of 16.6 million km² of ice-free land (Jones et al., 2010). In North America, most of Alaska, Canada (between 48°N latitude in the east and 55°N latitude in western Canada), and the ice-free portions of Greenland are considered cold region soils. In Eurasia, the northern cold soils belt ranges from the lands north of approximately 50°N latitude in the east (near the Kamchatka Peninsula and in Siberia) to 60–65°N latitude in maritime influenced western Europe (Fig. 1).

The southern circumpolar region includes Antarctica and its outlying islands and archipelagos, and Chilean and Argentinian Patagonia south of 46°S. Despite having a large land mass (14 million km²), Antarctica contains a large proportion of ice-covered land, and therefore has a much smaller extent of ice-free cold soils (approximately 49,500 km², or 0.35% of the land area of Antarctica (Bockheim, 2014)). These southern circumpolar cold soils are largely confined to maritime regions, with large extents in

Fig. 1 Distribution of cold region soils defined by soil temperature regime (STR). The global distribution of soils with frigid, cryic, and gelic (inclusive of the subgelic, gelic, and hypergelic soil temperature classes) is represented (Soil Survey Staff, 2014). Data on soil temperature regime are from USDA-NRCS (2016). Bounded regions show areas of focus, including (1) the northern circumpolar region (north of 45 degrees), (2) the southern circumpolar region (south of 45 degrees), and (3) the Qinghai-Tibetan Plateau (QTP). The Arctic Circle (66°33'N), Antarctic Circle (66°33'S) and Equator (0° latitude) are shown as dotted lines.

the McMurdo Dry Valleys in Victoria Land, the Antarctic Peninsula, and outlying islands such as the South Georgia, South Sandwich, and South Shetland Islands (Fig. 1).

Increases in altitude allow cold region soils to persist at lower latitudes. Although of moderate extent, southern extensions of cold region soils exist in the North American Rocky Mountains to latitudes as low as 36°N, and in Europe they persist throughout the European Alps and in isolated pockets of the Caucasus Mountains. In Asia, the largest expanse of altitude-driven cold region soils occurs in the Altai Mountains of Russia and Mongolia, the Tian Shan, Pamir, and Hindu Kush Mountains of China, Kyrgyzstan, Tajikistan, Pakistan and Afghanistan, and across nearly the entire extent of the Qinghai-Tibetan Plateau, a land area of ~1.5 million km² (Fang et al., 2015), reaching the southern flank of the Himalayas in India, Nepal, and Bhutan to 28°N. Low latitude cold soils occur in South America throughout the Andes mountains, stretching from Tierra del Fuego to as far north as Peru. Isolated pockets of cold soils exist on Mauna Loa and Mauna Kea on the island of Hawaii, and on the African continent near the summits of Mt. Kenya and Kilimanjaro, the tallest of the Rwenzori mountains in the Democratic Republic of Congo, and the High Atlas of Morocco (Fig. 1).

Characteristics of cold region soils

Physical processes and properties

Of critical importance to understanding the properties and development of cold region soils are the physical processes of heat transfer, water movement, and phase changes of water, all of which affect the rate and depth of thaw in cold region soils, the presence or absence of permafrost, and influence soil morphology and soil properties. The thermal properties of soil materials (in particular thermal conductivity) are important because the degree and intensity to which soils experience cryogenic processes in cold regions depends in large part on the materials that they are comprised of. The importance of the thermal properties of soil materials on soil temperature is largest at lower latitudes and decreases as latitude increases and the climate becomes colder. Snow depth and composition are additional dynamic factors that can affect the thermal regime and mean annual soil temperature. Snow is an excellent thermal insulator, and soils in areas that receive large, early snowfalls may remain relatively warm throughout the winter. In contrast, soils in areas that receive little to no snow or late snowfalls will freeze back much more rapidly in the winter.

Permafrost

A unifying characteristic of cold regions as defined here is the presence of sporadic to continuous permafrost, which is defined as the thickness of soil, surficial deposits, or bedrock below the surface of the Earth where temperature has remained below 0 °C for at least two consecutive years. In the northern circumpolar region, permafrost is generally ice-cemented. There are, however, locations in mountainous areas, on the Tibetan Plateau, and Antarctica where water or ice is present only at the contact points of the soil particles as hygroscopic water, a condition referred to as dry permafrost (Bockheim and Tarnocai, 1998).

The shallowest depth below the soil surface where materials have remained below 0 °C for at least two consecutive years is considered the top of the permafrost, or permafrost table. During the growing season, heat is transferred from the atmosphere into the soil, and the thawing front proceeds downward. This heat transfer continues until the end of the growing season, when freeze-back can occur both from the soil surface and from the permafrost table below. The active layer is the thickness of the soil above the permafrost table that is subjected to seasonal freeze and thaw. In the northern hemisphere, seasonal thaw usually begins in snow-free areas in April through to early June, but by late September seasonal thaw has largely reached its maximum, even though soils may remain unfrozen well into October or even later under certain conditions. The depth of this seasonal thaw may be less than 30 cm in the far north, but within the northern fringes of forested areas it may extend to depths of 150 to 250 cm or more. In parallel, seasonal thaw in the southern hemisphere begins around October or November and reaches a maximum by February before the onset of the southern winter, although in some ice-free regions of Antarctica temperature may not rise above 0 °C at any time during the year (Kimble et al., 2021). At some depth below the surface, the temperatures of soils, sediments, and rock begin to rise due to geothermal energy. The depth at which materials are no longer below 0 °C is considered the permafrost base.

Permafrost varies significantly in both thickness and extent. It underlies nearly all of the Arctic and Antarctic lands (continuous permafrost), including adjacent off-shore sectors, but underlies only some of the alpine, boreal, subarctic and subantarctic regions, depending largely on soil and ecological conditions (discontinuous or sporadic permafrost). Permafrost can extend hundreds of kilometers south of the tree line, and still much further south into high mountain areas at lower latitudes. The thickness of permafrost varies greatly, reaching thicknesses of more than 1200 m at a few locations in Siberia. However, most research in the field of soil science and soil survey is concerned only with the presence or absence of ‘near-surface’ permafrost, typically defined in soil survey and soil taxonomic systems as permafrost within 2 m of the soil surface (Soil Survey Staff, 2014; IUSS Working Group WRB, 2015).

Permafrost can thaw or be degraded by increased heat flow into the soil. In the Pleistocene it existed across nearly all cold regions, but natural and anthropogenic climate warming during the Holocene, and human land use in cold regions have resulted in accelerated permafrost degradation (French, 1999; Biskaborn et al., 2019). All else being equal, soils with thin surface organic materials, coarser (sandier) textures, large amounts of coarse fragments, and wetter conditions experience increased temperatures and thus are less likely to have near-surface permafrost. Soils with finer textures, thicker and less decomposed organic materials, fewer coarse fragments, and lower moisture content will tend to have colder mean annual soil temperatures or shallower permafrost (if permafrost is present). At the landscape scale, however, these conditions rarely exist independently. For example, wet soils often have thick surficial organic materials, but also increased moisture and extensive subsurface hydrologic flow. The influence of these multiple factors ultimately controls the soil thermal balance and determines whether or not near-surface permafrost is present.

Freezing point depression and water movement in freezing soils

At the end of the growing season, the freezing front moves downward through the active layer and the solid and liquid components of the soil begin to cool. Although the freezing point (the temperature at which a substance turns from liquid to solid) of pure, free water is 0 °C, the freezing point of water in soils is depressed below 0 °C. The phenomenon of freezing point depression in soils depends largely on solute concentration of the soil water (related to soil salinity), the antecedent soil water content, and pore-size distribution of the soil.

Increasing solute concentration in the soil water depresses the freezing point because ions disrupt the nucleation and organization of water into a solid, crystalline phase. Soil pore-size distribution affects the freezing point of soil water because water molecules adsorbed to soil particles have lower free energy. This means that soils with smaller pores (finer textured soils) will, in bulk, experience greater freezing point depression than soils with larger pores (coarse textured soils) where a significant proportion of the water molecules exist far from the surfaces of solid particles and therefore are at higher energy states. Antecedent water content influences freezing point indirectly through the distribution of soil water in pores of different sizes. The collective result of these phenomena is that soils with high salinity and a greater proportion of smaller pores can experience freezing point depression to temperatures of less than –20 °C. Thus, under almost all natural conditions, it is possible for a significant amount of unfrozen water to exist in soils at temperatures below 0 °C.

The presence of liquid water in soils below 0 °C results in several important phenomena. First, this liquid water provides an opportunity for microbial life to continue slowly on in an otherwise static, solid matrix. Second, it means that it is possible for water to move even when soil temperatures are below 0 °C. When soil freezes, water migrates towards the freezing front, and this results in the formation of segregated ice (ice inclusions in soil that separate or segregate soil particles)—which can take the form of ice veins, lenses, bands, or crusts—across a wide range of spatial scales (French and Shur, 2010). This movement of liquid water towards the freezing front results in the growth of segregated ice that is much larger than can be accounted for by the volumetric expansion of water alone. The growth of segregated ice bodies also means that, in ice-cemented permafrost, the upper permafrost tends to be more ice-rich than both the soil above it, which is often desiccated from water movement towards the permafrost table, and the soil well below the permafrost table, which does not generally experience water influx.

Morphological properties

The physical processes described above result in both permafrost and non-permafrost soils in cold regions having a unique set of morphological properties that differ significantly from those of temperate and tropical regions due to freeze-thaw cycles and the presence of either seasonally frozen ground or permafrost. Permafrost has a profound effect on soil morphology because it acts as a barrier to the movement of water and other materials and contributes to the increased intensity of cryoturbation (the physical translocation of soil materials by freeze-thaw processes). In addition, in ice-cemented permafrost, a saturated zone forms above the permafrost table during the growing season, which results in reducing conditions that lead to grayish (depletions) or bluish (gleyed) redoximorphic features in the upper soil.

Structure

When soil freezes, soil water moves to the freezing front forming a thin layer of ice called an ice lens. Because water moves towards the freezing front, the progressive freezing of soils can create a stratified fabric that consists of alternate layers of soil and ice lenses. Thus, a distinctive, platy, cryogenic soil structure can form in the early stages of this process, and after repeated freeze-thaw cycles finer soil particles become oriented along the plate surfaces. With time, the expansion of ice deforms the flat plates into discontinuous, small, curved plates referred to as 'lenticular' fabrics by geocryologists (French and Shur, 2010). In both seasonally frozen and permafrost-affected soils, a crusty or crumb-like structure at the soil surface is also common caused by needle-ice formation during early winter when water is extracted from below and freezes at the soil surface. Ice formation during freezing cycles can also cause a granular cryogenic soil structure to form in surface mineral materials (Fig. 2).

In cold region soils without permafrost, the effect of cryogenic processes on soil structure is largely limited to the topsoil and upper subsoil. Freeze-thaw cycles can fragment larger soil aggregates, increase soil pore connectivity, or consolidate and reinforce existing soil aggregates. In addition, under some conditions the annual formation of ice lenses in the upper subsoil can lead to the development of platy soil structure, which is maintained or reinforced by annual near-surface ice lens formation, provided that biological activity does not disrupt them during the growing season.

One of the most striking morphological components of permafrost-affected soils is the presence of visible, excess ice in the soil profile (Ping et al., 1998). In soils with ice-cemented permafrost, it is important to distinguish between cryostructures (patterns made by inclusion of visible ice that segregate the soil particle) and post-cryogenic soil structure (the structure of soil aggregates formed by cryogenic processes) (Ping et al., 2004). In regions with prevalent near-surface permafrost, soils generally have more strongly expressed cryogenic structure. Commonly an ice-rich layer occurs just below the permafrost table in soil which used to be part of the active layer because of water movement and subsequent desiccation. At the permafrost table, there is often a zone with horizontal and vertical cracks like an ice net (Fig. 3) (Ping et al., 2008). Here, an angular, blocky structure forms and, in the lower portions, the ice-rich layer often contains more than 70% ice. The mineral soil blocks seem to be 'floating' or suspended in the ice matrix (French and Shur, 2010; Ping et al., 2008). When the permafrost table drops and the soil becomes unsaturated, a rectangular-shaped lattice can form reticulate structures (Fig. 3).

Fig. 2 Representative examples of cryogenic soil structures observed in the active layer in soils with near-surface permafrost: (A) Example of contrasting cryogenic soil structures in active layer materials; A horizons (top and bottom of image)—moderate coarse subangular blocky, and C horizons in lacustrine material (center of image)—strong very fine to fine angular blocky structure. (B) Strong very fine to fine angular blocky cryogenic soil structure in the lower active layer. (C) Moderate to strong very thick platy structure in an A horizon. (D) Strong medium to thick platy structure remains after ice lenses melt in a frozen sample following removal of a core from the lower active layer. All photos by N. Cryoturbation

Cryoturbation, by strict definition, refers to the mixing (-turbation) of soil materials by freeze-thaw (cryo-) processes. In practice, the term cryoturbation is used as an umbrella to refer to the wide range of specific physical mechanisms that can result in unique morphological patterns observed in cold region soils, such as irregular or broken horizons, involutions, the accumulation of organic matter at the permafrost table, oriented rock fragments, and silt caps on rock fragments (Soil Survey Staff, 2014). Many of these physical mixing mechanisms do not truly homogenize the soil. Indeed, unlike other heavily turbated soils in temperate or tropical regions that have been homogenized by the shrinking and swelling of clays (Vertisols) or by extensive biological activity (through the action of macroarthropods or ground-dwelling mammals), cryoturbated soils retain distinct ‘packages’ of organic and mineral materials that have been physically translocated in a wide range of patterns and orientations (Ping et al., 2015). Cryoturbation is a common phenomenon in permafrost-affected areas but can also occur in non-permafrost cold region soils, for example in the alpine zone, where the soils are subjected to strong freeze-thaw cycles but lack permafrost.

The major mechanisms that result in the morphological patterns identified as cryoturbation are frost cracking, soil deformation and warping from the growth of ground ice, increased pore water pressures exerted on unfrozen soil as a result of confinement by frozen materials, the flow of less dense materials through and over more dense materials (diapirism, Swanson et al., 1999), differential frost heave (including frost jacking and frost sorting), and the movement of dissolved organic matter or retinization of saturated or dissolved organic materials (Dimo, 1965). Although these processes overlap and may operate together in cold region soils, environmental factors dictate their prevalence and intensity which influence the morphological manifestation of cryoturbation features in the soil. Because many of these mechanisms result in the net downward transfer of surface organic-rich materials to the upper permafrost, cryoturbation is a critical process for generating the large stocks of soil organic carbon that are found in cold regions in general, and particularly in northern latitude permafrost-affected soils (Koven et al., 2009) (Fig. 4).

- Frost-cracking and warping from the growth of ground ice or segregation ice.

In many areas affected by permafrost, the ground cracks due to cold and dry conditions. These cracks provide important opportunities for water and surface organic materials to enter the subsurface, particularly if seasonal ice occupies the cracks and, once thawed, saturated organic materials can move downward through viscous flow into the subsoil. Frost cracking in a primary sense is therefore an important mechanism for generating cryoturbation features in soils. However, the evolution of cracks in newly exposed parent materials, reinforced over long time periods, also dictates ground ice patterns which can warp and distort soil horizons. Once an initial crack forms, subsequent cracks curve to intersect it at near right angles, which maximize strain energy release. Repeated opening and closing of cracks (occurring with annual freeze-thaw cycles in cold environments) results in curving of the initial intersections, resulting, eventually in a unique polygonal pattern on the land surface (French and Shur, 2010). Each year liquid water enters the cracks and freezes in the winter, resulting in the growth of vertical ice veins, which eventually thicken and become ice wedges. The formation of ice wedges increases the internal volume of the soils, and the soils buckle up at the edge of the polygons. In the process, the horizontal soil horizons become warped and distorted (Fig. 4).

- Increased pressures exerted on unfrozen soil as a result of confinement by frozen materials (hydrocryostatic model) and the flow of less dense materials through and over more dense materials (diapirism).

Fig. 3 Representative examples of cryostructures observed in ice-cemented permafrost-affected soils of the Subarctic and Low Arctic. (A) Ataxitic (suspended) cryostructure with 2–3 cm ice belts (Imnavait Creek, Alaska, N.A. Jelinski); (B) Parallel planar layered cryostructure (Utqiagvik, Alaska, C.-L. Ping); (C) Latent micro-lenticular cryostructure (Copper River Basin, Alaska, N.A. Jelinski). (D) Microporphyrific cryostructure (Copper River Basin, Alaska, N.A. Jelinski); (E) Coarse lenticular/ataxitic (suspended) cryostructure (Copper River Basin, Alaska, N.A. Jelinski); (F) Irregular reticulate cryostructure (Franklin Bluffs, Alaska, C.-L. Ping). (G) Micro-braided cryostructure in organic materials (Copper River Basin, Alaska, N.A. Jelinski); (H) Very fine non-parallel wavy and medium crustal cryostructure (Copper River Basin, Alaska, N.A. Jelinski); (I) Wedge ice with threads or foliations of organic materials (Franklin Bluffs, Alaska, C.-L. Ping).

The re-freezing of soils from the top down at the end of the growing season can result in moist, unfrozen materials being squeezed between a freezing front and the permafrost. This can generate confining pressure that can push, deform, or extrude plastic or viscous materials through preferential planes of weakness or cracks in the soil. In extreme form, this hydrocryostatic process can result in the extrusion of subsoil materials at the soil surface. In addition, inversions of bulk density are common in permafrost-affected soils. The general prevalence of ice-rich upper permafrost (due to water movement towards the freezing front

Fig. 4 Morphological manifestations of cryoturbation processes in the Subarctic and Low Arctic. (A) Example of extreme variability in organic layer thickness and morphology due to differential frost-heave in association with a patterned ground feature (in this case stripes) (Imnavait Creek, Alaska, N.A. Jelinski); (B) Deep post-fire cryoturbation of organic-rich materials overprinted with recently developed lenticular cryostructures (Copper River Basin, Alaska, N.A. Jelinski). (C) Ice-rich footslope soil showing mixing of organic-rich materials and underlying mineral materials in diapiric forms (Imnavait Creek, Alaska, N.A. Jelinski); (D) Downward movement of organic materials through vertical cracks in the upper permafrost (Sagwon Hills, Alaska, N.A. Jelinski); (E) Cryoturbation in a shallow permafrost soil showing movement of organic-rich materials due to diapiric and solutioning mechanisms (Copper River Basin, Alaska, N.A. Jelinski); (F) Deformation of alternating organic and mineral layers due to ground ice (wedge ice) (Sagwon Hills, Alaska, N.A. Jelinski); (G) Mixing of organic-rich and mineral materials in the active layer (Copper River Basin, Alaska, N.A. Jelinski); (H) Mixing of organic-rich and mineral materials in the permafrost (Copper River Basin, Alaska, N.A. Jelinski).

and desiccation of the lower active layer) can result in less dense, water-rich materials 'below' more dense materials in upper soil horizons, setting up conditions for diapirism (Swanson et al., 1999), the buoyant upward movement of less dense materials through the planes of weakness in more dense materials above them. This results in unique, swirling and or mushroom-like diapiric forms that can range from micro- to macro-scales (Fig. 4).

- Differential frost heave (including frost jacking and frost sorting).

Due to differences in the thermal conductivities of various soil materials and coarse fragments, freezing and thawing fronts can penetrate the soil at dramatically different rates. Mineral soils, particularly those with a high proportion of coarse fragments, will experience accelerated rates of freezing or thawing front penetration relative to soils that have thick organic materials at the surface. Differential frost heave occurs when soils with little to no surface organic materials freeze back faster at the end of the growing season than immediately adjacent soils with thick organic cover. This situation occurs most commonly in patterned ground configurations such as non-sorted circles, sorted circles, and stripes. When mineral soils or those rich in coarse fragments begin to freeze, liquid water migrates upwards and inwards to join the freezing front. This results in the growth of ice lenses, which can significantly increase the volumetric expansion of the soil, resulting in heave of the ground surface (frost heave) relative to the adjacent, organic covered soil. Differential frost-heave can therefore increase the elevation of mineral materials relative to adjacent organic materials and generate micro-colluvial movement which can 'bury' or 'roll over' the adjacent organic materials, subducting them to the permafrost table over many cycles. This mechanism of cryoturbation is perhaps one of the most widespread at the landscape scale and has been used to explain the ubiquitous organic rich materials associated with the permafrost table in the Arctic. The differential frost heave process also can play a role in situations where fine-earth mineral soils and coarse fragments interact. For example, frost sorting of coarse fragments into sorted circles or stone nets and the frost jacking or orientation of individual coarse fragments also occurs due to differences in freezing front penetration and ice growth between soil material in contact with the coarse fragments and those further away.

- *Leaching or retinization of saturated or dissolved organic materials.*

As soils thaw during the growing season, surface or subsurface organic materials which are saturated can become viscous and mobile. This allows them to move downward through macropores between soil aggregates (solutioning). In addition, stagnant water interacting with organic-rich soil horizons in the upper horizons can pick up significant amounts of dissolved organic matter. As the soil thaws, this water proceeds downwards to the permafrost table, where it stops. This downward movement of dissolved organic matter to the permafrost table has been termed 'retinization' in the Russian literature (Dimo, 1965).

Redoximorphic features

If soil drainage is impeded during thaw and snow melt due to underlying seasonal frost or permafrost, the topsoil remains saturated for longer than the underlying zone. These episaturated conditions can produce reduced and gleyed features near the top of the profile because of the physical effect of frozen materials on impeding the downward movement of water, which is unique to cold regions (United States Department of Agriculture, Natural Resources Conservation Service, 2018). In addition, in soils with permafrost, the permafrost table acts as a barrier to water and roots during the growing season, thus creating a reduced matrix because the water table perches above the permafrost. Thus, the lower active layer in permafrost-affected soils is often gleyed (Fig. 5). Iron reduction in anoxic conditions in soils is a biochemical process, and the presence of significant redoximorphic features in cold region soils is direct evidence of the effect of psychrophilic anoxic microorganisms continuing to function near or below the freezing point of water.

Patterned ground

Cryogenic processes result in self-organized micro landforms known as patterned ground. This self-organization of vegetation and coarse fragments vary across these micro landforms, which may appear "sorted" or "unsorted". 'Patterned ground' is a group term for symmetrical forms such as circles, polygons, hummocks, nets, steps, and stripes. Various terms have been used to describe these patterns, such as 'rutmark,' 'ra~mark,' 'frost polygon,' 'struk- turboden,' 'polygonboden,' 'ice-wedge polygon,' 'stone polygon,' 'soil circle,' 'mud circle,' 'stone ring,' 'stone stripe,' 'hummocky ground,' 'frost boil,' 'ice mound,' 'earth hummock,' and many others. One of the most common forms of patterned ground in Arctic regions are ice-wedge polygons. The ground develops a series of ice wedges that result from soil frost cracking in winter and water freezing in cracks. The ice wedges tend to increase in size year after year and exert strong lateral forces that result in a buckling of the polygons. Changes in elevation of the soil surface adjacent to ice wedges results in formation of the so-called low-center polygons in which the center of the polygon is depressed. Other polygon types, such as high-centered polygons, can form when ice wedges degrade and the soil adjacent to them subsides, leaving a high, dry polygon center with lower outer troughs.

Non-sorted circles or frost boils are common throughout permafrost regions, especially where the soils are of medium to clayey texture (Walker et al., 2004). Frost boils appear on the ground surface as areas of the mineral soil material 'boiled' from underneath the surface, forming circles (Fig. 6). The vegetation cover is most abundant on the edge and outside of the frost boil. Although there are many theories as to how frost boils form, field morphology suggests that it is due to differential frost heave and diapirism. In a well-developed soil profile of a frost-boil, it is evident that organic matter has been cryoturbated into the lower soil horizons (Fig. 6). Even though the processes of formation involved in earth hummocks and frost boils may not be the same, they all result in

Fig. 5 Redoximorphic features in permafrost-affected soils of the Subarctic and Low Arctic. (A) Strong near-surface gleying (indicating biochemical iron reduction) in an otherwise oxidized upland soil—these conditions are induced when thaw depth is shallow early in the season and the soil becomes saturated due to perched water (Imnavait Creek, Alaska, N.A. Jelinski); (B) Reduced pore linings in an upland soil due to seasonal saturation and iron reduction (Fairbanks Area, Alaska, N.A. Jelinski); (C) Strongly gleyed material formed due to saturation above the permafrost table underlying more oxidized upper horizons in a core from a permafrost-affected soil (Copper River Basin, Alaska, N.A. Jelinski) (D) Low chroma, high value (gray) depleted matrix underlying a surface organic horizon in a permafrost-affected soil with a shallow saturated zone (Copper River Basin, Alaska, N.A. Jelinski); (E) Example of rapid color change in organic materials of a Low Arctic drainage basin upon exposure to air—the bright orange material in the center of the photo represents frozen organic materials upon immediate excavation from a soil pit before exposure to oxygen, while the darker materials above and below are the same frozen organic materials after exposure to oxygen for approximately 3 h. This rapid color change is likely due to redox reactions involving manganese and sulfate (Arctic Foothills, Alaska, N.A. Jelinski).

similar soil morphology: cryoturbated organic matter in the lower horizons and warped and broken soil horizons (Walker et al., 2004). Other sets of cryogenic processes related to soil freezing and thawing can result in the development of stone rings (sorted circles). These stone rings can form entirely in coarse fragments, or from an upwelling of the mineral material in the form of a core of raw, earthy material and an outward displacement of the coarser rock fragments (Fig. 6).

On sloping land, there are many elongated forms of patterned ground that result from at least two processes: frost sorting and solifluction (the slow gravity-driven downhill movement of saturated soil). Patterns include stone garlands, stone stripes, soil stripes, and others (Fig. 6). Where solifluction is intense, the genetic soil horizons become highly deformed and often completely obliterated in the upper solifluction lobe.

Fig. 6 Representative examples of patterned ground features in Arctic environments. (A) Sorted circle with fine-earth center and coarse-fragment dominated stone outer ring (Brooks Range, Alaska, N.A. Jelinski); (B) Sorted circles (stone rings) formed solely in coarse fragments (Prince Patrick Island, Canada, J.C.F. Tedrow); (C) Mud boil in glacial sediments (Atigun Valley, Alaska, N.A. Jelinski); (D) Non-sorted circles (frost boils) in northern Alaska (J.C.F. Tedrow) (E) Low-centered ice-wedge polygons (Arctic Coastal Plain, Alaska, G. Iwahana); (F) High-centered ice wedge polygons (Prince Patrick Island, Canada, J.C.F. Tedrow) (G) Stone stripes (Brooks Range, Alaska, N.A. Jelinski); (H) Solifluction lobes (Bering Land Bridge National Preserve, D.K. Swanson).

Biological and chemical properties

On an aerial basis, the accumulation of organic carbon in soils of cold regions (particularly the northern circumpolar) exceeds that of any other soil regions on earth. Cold region soils may contain 30–40% of the global stock of soil organic carbon to a depth of 3 m (Hugelius et al., 2013; Ping et al., 2015). The generally cold and moist conditions in cold region soils slow microbial respiration and the decomposition of organic matter. These conditions, in addition to cryoturbation processes, explain why cold region soils store large amounts of carbon even though inputs from aboveground biomass are small.

Temperature and moisture affect the accumulation and distribution of C stocks in the soil profile through controls on vegetation, cryogenic soil processes (such as cryoturbation) and the presence of or depth to permafrost. In addition, the landscape-scale effects of cold temperatures and reduced evapotranspiration in cold regions has resulted in the development of large peatland complexes. Most of these organic soils are in the boreal regions in the Northern Hemisphere: northern Russia, the Canadian Shield, and interior Alaska. Based on recent studies, average organic carbon stocks stored in the peatlands of the northern circumpolar region may exceed 100 kg C m^{-2} (Hugelius et al., 2020). Additionally, in the mineral soils of the Arctic, nearly 50% of the total organic carbon may be stored in the upper permafrost as the result of cryoturbation (Ping et al., 2015). Thus, cryoturbation contributes to the sequestration of atmospheric carbon into the upper permafrost (Koven et al., 2009).

The character of soil organic matter (SOM) in cold soils is influenced by its cryogenic environment, its position in the soil profile, the surface, subsurface soil active layer, and the presence of permafrost. In general, the SOM in cold soils is less decomposed than that in temperate and tropical regions. The SOM in arctic soils can be separated into extractable (EF) and non-extractable fractions (NEF) based on alkali solubility. The NEF, containing cell wall and related constituents, such as hemicellulose and soluble fibers, dominate the SOM of cold soils (Dai et al., 2002). The largest proportions of NEF occur in the SOM of the upper permafrost and this fraction may have a greater potential to influence carbon cycling than EF in these ecosystems with climate warming.

Chemical weathering of most soil parent materials in cold regions tends to be shallower and less intense than in temperate and tropical regions. Permafrost and seasonal freeze-thaw cycles mean that leaching, chemical transformation, and biochemical weathering is limited in most cold soils, relative to soils of temperate and tropical regions. Most cold region soils tend to be relatively unweathered and rich in 2:1 phyllosilicates such as micas, illites, etc. (Ito and Wagai, 2017). Chemical transformation and clay neoformation from weathering rarely extends beyond the formation of mixed 1:1 and 2:1 minerals. Phyllosilicate minerals that indicate more advanced weathering such as kaolinite can occur in cold regions, however they are often inherited from the parent materials rather than produced from mineral weathering in situ (Borden et al., 2010). Although chemical transformations are limited, given sufficient time and appropriate environmental conditions, measurable weathering of soil minerals has been observed even in the coldest regions on Earth (Gibson et al., 1983). Iron oxidation in particular is prevalent across all cold regions, including the cold desert zones of Antarctica (Ugolini et al., 1990; Bockheim, 1997). These biochemical weathering processes are greatest at lower latitudes in cold regions and gradually decrease at higher latitudes.

Effects of land use and climate change on cold region soils

Cold region soils present a special challenge to land use and management owing to the effects of frost heave, the presence of massive ground ice, and accelerated thaw due to natural and anthropogenic climate warming. These issues have caused problems for construction, development and maintenance of transport, structure and foundation instability, and challenges to agricultural development (Hjort et al., 2022). With cold temperatures and short growing seasons, vegetation takes longer to recover after disturbance, and the unique species of wildlife and ecosystems associated with cold soils are globally unique and highly sensitive to ecological change. Natural resources extraction, mainly oil, gas, and minerals, has increased pressure from development and disturbance in cold regions. Optimum solutions for ensuring environmental sustainability lie within our understanding of these cold soils and their environment.

Climate change

The global extent of permafrost and cold region soils has generally decreased throughout the Holocene (Li et al., 2021), however accelerated warming and permafrost degradation is changing cold regions on a massive scale (Biskaborn et al., 2019). This has major implications for cold region soil conservation and development. Cold region soils and permafrost-affected soils in particular hold a significant proportion of the total terrestrial soil carbon stock (Hugelius et al., 2013). Warming may result in the increased release of carbon from permafrost to the atmosphere as microbes become more active and degrade the soil carbon formerly stabilized by cold ground temperatures. This carbon release may potentially offset any major gains in the reduction of anthropogenic carbon emissions and it is therefore of great importance that these cold region terrestrial emissions are constrained (Natali et al., 2021). In addition, the impacts of surface subsidence in regions with massive ground ice (thermokarst) may have far-reaching ecological and biogeochemical consequences, and pose a major threat to cold region infrastructure (Murtin, 2009).

Engineering and development

Infrastructure development in cold regions generally leads to an increased active layer thickness and deeper permafrost, and this results in changes in leaching, oxidation and reduction, and cryogenic processes. In the boreal regions, where permafrost is discontinuous and thin, general practice is either to thaw the permafrost or to insulate it to minimize the effects of frost damage. But in the Arctic region, the best practice is to insulate the permafrost to avoid thawing. Thick beds of gravel are applied for

insulation, and a lighter-color pavement is used to decrease absorption of solar radiation. For permanent structures and houses, gravel pads or insulated foundations are commonly used in soils containing only ice lenses. But in areas where the soils have a large ice content, piling is used for structures and houses. In some cases, the piling or foundation is refrigerated to avoid heat conduction to the permafrost.

Vegetation tends to be slow to recover from disturbance in cold regions because of short growing seasons and cold temperatures. This is especially true in the Low and High Arctic and in the Antarctic, where the result of surface disturbances such as compaction and tracks from vehicles, even when travelled in the winter, can have long lasting effects on vegetation cover, soil thermal regime, the soil biological community, and localized hydrology (Kevan et al., 1995).

Agriculture

Soil affected by permafrost accounts for more than 10% of the exposed global land surface (Obu, 2021). Most of these areas are, in their natural state, tundra, boreal forest, cold deserts, and bogs. However, some areas have been cultivated for a long time. Cold soils present a great challenge to agricultural development not just because of the low temperatures, but because of the presence of ice. In the subarctic or boreal regions, farms newly cleared from native forest with underlying permafrost often face subsidence. The land surface may become hummocked because of melting of ice wedges and even thermokarst sinkholes, where large volumes of ice are present. Such problems are more severe on Pleistocene surfaces because of the larger ice content (Desyatkin et al., 2021). Holocene terraces are generally more favorable for land-clearing and farming.

The native peoples of the circumpolar regions have used Arctic lands for animal production (both wild and managed) for millennia. These people include the Samis in northern Scandinavia, the Inuit in northern Alaska and Canada, and the Chukchi people in northern Russia. In the alpine and plateau regions, the Tibetans raise yaks, sheep, and cattle on the Tibetan Plateau; the native peoples of the Andes have long raised llamas and other domesticated animals. In recent years there have been concerns of overgrazing in these fragile ecosystems. Once the organic layers or the surface vegetation covers are disturbed or destroyed, the quality of the land deteriorates owing to topsoil erosion.

Agriculture in the circumpolar region is made possible because of the long daylight hours in the summer that enable crops to mature in a shorter time than in temperate regions. In the boreal regions, where the soil conditions are favorable, small grains, especially barley (*Hordeum vulgare* L.), can mature within 110 days, and oats (*Avena sativa* L.) within 130 days. Vegetables, such as carrots (*Daucus carota* L.), lettuce (*Lactuca sativa* L.), and cabbages (*Brassica oleracea* L.) can be harvested in less than 60 days. Potatoes (*Solanum tuberosum* L.) can be grown more than 200 km north of the Arctic Circle, where the permafrost table persists at less than 1 m from the surface. Such intensive agriculture can only exist in high-latitude environments because of the prolonged daylight and warmer summer temperatures, however, and not in alpine and plateau environments that experience strong diurnal temperature changes; the temperature can reach more than 20 °C at midday but drop below freezing at night.

The greatest concern of farming in soils affected by permafrost is subsidence. These soils contain variable amounts of ice, therefore, once the soils are stripped of their natural vegetation cover the thermal regime changes and the soils will warm. In soils with a large ice content and ice wedges, thermokarst will occur, and cleared fields become hummocky, resulting in difficult management. Another concern is the nature of the substratum. When the land is cleared, water from the melted ice must be drained or waterlogging or ponding will occur if there is a hydrologically restricting layer, or the land is on a topographic low. Thus, good understanding of the soil and the geographic environment is the key to successful farming in cold soils.

Conclusion

The properties of soils in cold regions are distinctive, and controlled by unique physical and biochemical processes. These processes have resulted in soils that are generally high in organic carbon and have experienced limited chemical weathering. This accumulation of organic carbon has resulted from slow microbial decomposition from cold temperatures, and the physical translocation of organic rich surface materials downward through cryoturbation. However, despite these cold temperatures, biochemical reactions continue and have significant effects on soil morphology and properties. The heterogeneous nature of cold region soils over short distances is linked closely to patterned ground formation and ground ice content, particularly in permafrost regions. These large stocks of organic carbon, the formation of ground ice, and unique biochemical properties make cold region soils highly sensitive to environmental and anthropogenic change. As climate change and human land use accelerate in cold regions it is critical that the body of knowledge on cold region soils continues to be synthesized, improved, and utilized to maximize ecological health and sustainability.

Abstract

Cold region soils are strikingly beautiful, highly diverse, globally important and increasing affected by anthropogenic activities and climatic change. In this chapter, we examine the global distribution and unique and diverse characteristics of these soils through a focus on their genesis and classification in each of the three major zones of cold region soils (the Northern Circumpolar, Southern Circumpolar, and Qinghai–Tibet Plateau). By highlighting the variable formation of cold region soils around the world, we can identify gaps in our knowledge of them and enable better prediction of the future trajectory of these soils as they respond to change.

Key points

- Cold region soils are globally distributed and highly diverse
- Soils of the three major cold regions (the Northern Circumpolar, Southern Circumpolar, and Qinghai–Tibet Plateau) share some similarities but differ in critical ways.
- Soil forming factors in cold regions are aligned along latitudinal gradients (in the Northern and Southern Circumpolar) and with elevation (in low latitude Alpine regions and the Qinghai–Tibetan Plateau), allowing a general understanding of the distribution and properties of cold region soils.

Introduction

The soils of cold regions are highly diverse. They hold globally important terrestrial carbon stocks, affect local and regional hydrology, and support ecosystem functions at high latitudes and altitudes. An understanding of their distribution and properties can only come from detailed study of the unique set of factors that has shaped these soils both within and across cold regions. Although united by similar sets of biophysical and chemical processes that operate in cold environments, the genesis of cold soils is far from homogeneous. The beauty and complexity of these soils becomes apparent when taking a global perspective on their distribution, genesis, and classification.

Genesis and classification of cold region soils

General frameworks for understanding the genesis of cold region soils have been constructed by evaluating the common processes of their formation and spatial trends by climatic or geographical zones (Ugolini, 1986; Bockheim and Ugolini, 1990). In this

chapter we take a zonal approach, similar to previous authors, to identify broad trends in soil genesis and soil forming factors between cold regions. It is important to note that the zonal approach applies primarily to well-drained soils under representative climate and vegetation types, and that regional soil diversity is always much greater than implied by zonal characterizations (Tedrow, 1977). Therefore, we also attempt to illustrate some of that regional variation within the zonal framework. Despite the inherent limitations of the zonal approach, it provides a framework to understand the major trends in pedogenesis necessary for a global perspective. When using taxonomic names in this discussion, we provide both the taxonomic name in the US Soil Taxonomy (Soil Survey Staff, 2014) and World Reference Base for Soil Resources (WRB, IUSS Working Group, 2015), with the WRB name provided in parentheses.

Northern Circumpolar soils

The Northern Circumpolar Region (NCR) contains more than 17 million km² of ice-free cold region soils, which is the largest area of ice-free cold region soils in the world. We refine the generalized NCR pedogenic zones of Tedrow (1977) and Ugolini (1986) with the addition of spatial information from the Circumpolar Arctic Vegetation Map (CAVM) bioclimate zones (Walker et al., 2005), and include Boreal regions with frigid STRs (soil temperature regimes, US Soil Taxonomy, Soil Survey Staff, 2014) to 45° latitude. We subsequently group the NCR into the Boreal and Subarctic zone (including frigid STRs to the Boreal/temperate boundary), the Low Arctic zone (CAVM bioclimate zones D and E) and the High Arctic zone (including the polar and subpolar deserts (Ugolini, 1986, Tedrow, 1977), and CAVM bioclimate zones A, B, and C)) (Fig. 1).

Parent materials

Despite the large ice sheets which covered all of Canada, Fennoscandia and western Europe during the last glacial maximum, many parts of the NCR remained ice-free throughout much of the Pleistocene. These ice-free areas include the Alaskan Interior and Alaska North Slope as well as the Lena river basin, Cherskiy and Verkhoyansk mountains, and Kolyama Lowland in northeast Russia. In areas covered by continental or mountain glaciers, NCR soils have formed predominantly in deposits such as glacial till, glaciolacustrine or glaciofluvial materials, while in areas not covered by ice during the last glacial maximum, soils are often blanketed by loess, pedis sediment, or colluvium of varying thickness or formed in alluvium or residual materials (Börker et al., 2018). Additionally, marine sediments exposed subaerially due to isostatic rebound are common in maritime regions of the northern coasts of Alaska, Canada, and Siberia.

Boreal and subarctic regions

Boreal and Subarctic soils are associated with frigid, cryic, and gelic mean annual soil temperatures (MAST; US Soil Taxonomy, Soil Survey Staff, 2014). The Boreal and Subarctic regions experience the warmest temperatures and highest precipitation of the NCR zones. Most of the southern Boreal is permafrost-free, while northern Boreal areas have isolated and sporadic permafrost, and the Subarctic is largely characterized by discontinuous permafrost.

- **Climate:** Climate in Boreal regions ranges from cold ultra-continental climates (such as mid-Canada and Siberia), to more moderate cold maritime-influenced climates in coastal areas. In the southern continental parts of the Boreal, average high temperatures may exceed 20 °C for several summer months, while for at least 3 months during the winter, average high temperatures are often below 0 °C in the same areas. In the wettest parts of the Boreal, annual average rainfall can exceed 800 mm year⁻¹ and significant snowfall (>2000 mm), with total precipitation as water equivalent exceeding 1000 mm. The continental Subarctic may experience average high temperatures >20 °C in summer from less than 1 to 3 months, and average high temperatures of -10 °C to -20 °C for much of the winter. Precipitation tends to be less than in the Boreal, with rainfall ranging between 200 and 400 mm, with an additional 50–200 mm water equivalent as snowfall. In general, two-thirds to over 90% of total precipitation in the Boreal and Subarctic regions occurs as rain during the growing season. In maritime influenced regions of the Boreal and Subarctic temperatures are moderated and precipitation is generally higher.
- **Vegetation.** Most upland soils in the Boreal and Subarctic have formed under coniferous forest dominated by one or two of four major Boreal tree genera (*Picea* sp. L. (spruce), *Abies* sp. L. (fir), *Pinus* sp. L. (pine), or *Larix* sp. L. (Larch/Tamarack), with ground flora dominated by cryptogams (mosses (bryophytes) and lichens). Coniferous needles and moss or lichen litter tend to be acidic, which reduces microbial decomposition and leads to the widespread accumulation of organic materials at the soil surface. The prevailing soil moisture, drainage, and temperature conditions dictate the thickness and decomposition state of these surface organic materials. They are excellent thermal insulators, are critical for regulating soil temperatures, and protect discontinuous, sporadic, and isolated near-surface permafrost across Subarctic and Boreal regions where permafrost would not otherwise persist.
